The generator should be removed and the leads completely freed from adhesions and sutures and dissected down to the venous entry site. If the patient is pacemaker dependent, a temporary pacing wire (normally introduced through the femoral vein) should have been placed ahead of time. The proximal end of the lead, which includes the connector pin, should be cut, and 1 cm of the lead inner coil should be exposed. A coil expander is used to remove any wire burs and to ensure patency of the lead lumen. A locking stylet should then be advanced into the lead inner coil until it reaches the distal tip of the lead. The locking mechanism is activated, and the outer lead insulation should be secured with a tie before introduction of the sheaths. If simple traction is not sufficient to free the lead from the myocardium once the locking stylet is in place, sheaths should be introduced to disrupt fibrous adhesions or scarring. Telescoping stainless steel sheaths (or other available sheaths, including excimer laser sheaths and, most recently, electrosurgical dissection sheaths) should be advanced over the lead down to the venous entry site, where they disrupt the scar tissue surrounding the lead. The sheaths should be advanced down under fluoroscopic guidance to the distal tip of the lead as continuous traction is placed on the locking stylet system. The lead tip may then be pulled

free by counterpressure and countertraction, and the entire lead is extracted. If this method is unsuccessful, another technique (e.g., extraction through the femoral vein) may be used.

Extraction through the Femoral Vein

The femoral vein approach is the preferred technique to extract lead remnants or broken or cut leads that are free-floating in the venous system, heart, or pulmonary artery.⁴³ It may also be used as a primary approach for transvenous extraction of permanent leads, especially if there is concern for pushing infected debris from the original entry site into the circulation. This approach engages angiographic catheters such as the angled pigtail catheter or a variety of snares (see earlier for different types of available snares) to grasp loose lead ends or the deflecting wire and Dotter retriever if no freed ends are available. Traction is applied to pull the lead (or lead remnants) from the heart, and the lead is then withdrawn from the body through the femoral vein sheath.

Complications

Serious complications may occur as a result of transvenous lead extractions. Complications may be intraoperative, perioperative (events that occur or are diagnosed within 24 hours after the procedure), postoperative (events that occur or are diagnosed after 24 hours but within 30 days of the procedure), or late (events that occur or are diagnosed more than 30 days after the procedure date). **Box 85-17** summarizes major and minor complications related to transvenous lead extractions.

MANAGEMENT OF CARDIAC DEVICES DURING AND AFTER SURGERY

Pacemakers

Application of a magnet over a pacemaker inhibits all sensing function of the pacemaker. The previously programmed pacing mode is subsequently transiently changed to DOO, VOO, or AOO until the magnet is removed. The magnet pacing rate varies according to the pacemaker manufacturer. The magnet may be used prophylactically before surgical procedures to avoid inappropriate sensing by the pacer as a result of noise artifact created by cautery. Other procedures during which there is a risk of inhibition of the pacer by inappropriate sensing of noise include electroconvulsive therapy, extracorporeal shockwave lithotripsy, and occasionally electric cardioversions.

Implantable Cardioverter-Defibrillators

Unlike standard pacemakers, defibrillators with backup pacing and pacemaker-defibrillators do not have their sensing function inhibited by a magnet. The magnet does, however, inhibit delivery of any antitachycardia therapy, such as ATP or high-energy defibrillation.

BOX 85-17 Major and Minor Complications Related to Transvenous Lead Extractions

MAJOR COMPLICATIONS

- Death
- Cardiac avulsion or tear requiring thoracotomy, pericardiocentesis, chest tube, or surgical repair
- Vascular avulsion or tear requiring thoracotomy, pericardiocentesis, chest tube, or surgical repair
- Hemothorax or severe bleeding from any source requiring transfusion
- Pneumothorax requiring chest tube drainage
- Pulmonary embolism requiring surgical intervention
- Respiratory arrest
- Septic shock
- Stroke

MINOR COMPLICATIONS

- Pericardial effusion not requiring pericardiocentesis or surgical intervention
- Hemodynamically significant air embolism
- Pulmonary embolism not requiring intervention
- Vascular repair near the implant site or venous entry site
- Arrhythmia requiring cardioversion
- Hematoma at the pocket requiring drainage
- Arm swelling or thrombosis of implant veins resulting in medical intervention
- Sepsis in a previously nonseptic patient with infection
- Pacing system–related infection of a previously noninfected site

OBSERVATION

- Transient hypotension that responds to fluids or minor pharmacologic intervention
- Nonsignificant air embolism
- Small pneumothorax not requiring intervention
- Ectopy not requiring cardioversion
- Arm swelling or thrombosis of implant veins without need for medical intervention
- Pain at cutdown site
- Myocardial avulsion without sequelae
- Migrated lead fragment without sequelae

Magnet inhibition of antitachycardia therapies prevents delivery of inappropriate ICD therapies during cautery or other procedures that could produce noise erroneously sensed by the lead as VT or VF. Although a magnet is applied to an ICD, causing inhibition of the programmed ICD therapies, the patient should be treated like any patient who does not have an ICD in the event that a tachyarrhythmia occurs. Alternatively, cautery (or other problematic procedures) may be transiently halted and the magnet removed from the ICD to allow implementation and delivery of programmed ICD therapies.

In addition, if a patient is pacemaker dependent, the pacing mode of the ICD should be reprogrammed to DOO, VOO, or AOO (as clinically indicated) before anticipated cautery. Alternatively, a temporary pacing

wire should be placed to avoid inappropriate sensing of noise and subsequent inappropriate inhibition of the pacing function of the ICD. Such inappropriate inhibition of pacing in a pacemaker-dependent patient could be catastrophic if it is not anticipated. After the procedure, the initial ICD parameters should be restored. In general, even if no reprogramming is necessary, ICDs should be interrogated after surgery or a magnet applied to confirm proper functioning and parameter settings.

Of note, some ICD generators are part of a magnet reed switch manufacturer recall and thus have their magnet function permanently turned off. For such generators, ICD therapies should be turned off before surgery expected to require cautery and turned back on after the procedure.

Structural Heart Disease

Idiopathic Ventricular Tachycardia

Atrial Fibrillation

Atrioventricular Junction Ablation

Catheter Ablation of Atrial Fibrillation

Cryoballoon Ablation of Atrial Fibrillation

Over the past 40 years, cardiac electrophysiology has progressed from an esoteric field dedicated to understanding arrhythmia mechanisms to an indispensable modality in the diagnosis and treatment of cardiac arrhythmias. Electrophysiology therapeutics first began with cardiac surgery for the treatment of arrhythmias. After it became clear that invasive surgical strategies could cure arrhythmias, methods for delivery of energy through catheter-based techniques were developed. The advent of catheter ablation has revolutionized the management of patients with tachyarrhythmias. Radiofrequency current has become the energy source of choice for catheter ablation and has made it the first-line therapy for the treatment of many tachycardias.

PROCEDURAL TECHNIQUE AND THE ELECTROPHYSIOLOGY STUDY

The electrophysiology study (EPS) is an indispensable prelude to catheter ablation allowing for the identification of tachycardia mechanism and the most appropriate site for energy delivery. The EPS involves placing electrode catheters in various chambers of the heart for recording, stimulation, mapping, and ablation. Femoral veins and arteries are the most common sites of vascular access used for EPS. Less commonly used sites include the antecubital fossa, subclavian, and jugular veins. Adequate local anesthesia is administered before vascular puncture. A 0.035-inch short J guidewire is placed via the percutaneous Seldinger technique into the femoral vein or artery just below the inguinal ligament. Additional

wires, up to three in a single vein, are placed 5 to 10 mm caudal to the first wire. Double- and triple-headed vascular access devices that can accommodate two or three catheters through a single access sheath are commercially available and are used in some laboratories. Hemostatic sheaths (size 6 Fr to 11 Fr) are placed over the guidewires, up to three in a single vein. If more than three catheters are required, another vein is used, typically the contralateral femoral vein.

For His bundle recordings, the femoral approach allows superior catheter stability. However, catheterization of the coronary sinus (CS) is more readily accomplished via the internal jugular, left subclavian, or left antecubital veins. The lateral antecubital veins that drain into the cephalic vein are avoided because of the right angle at which they enter the axillary vein, making catheter manipulation more difficult. These nonfemoral sites are usually reserved for patients with inaccessible femoral access or difficult CS cannulation despite attempting via the femoral approach with a steerable catheter, but in some laboratories, CS cannulation is routinely performed via the left subclavian vein or right internal jugular vein. Although accessing the CS through a femoral vein is generally more difficult, in experienced hands it can be readily accomplished either via a direct approach, often facilitated by bending the catheter in the hepatic vein to achieve a greater posterior angulation, using a steerable catheter, or more indirectly by forming a catheter loop within the right atrium.

The catheters used in an EPS are either steerable or nonsteerable woven Dacron or synthetic catheters containing electrodes that can be manipulated under

fluoroscopy in the cardiac chambers. Nonsteerable catheters are available in a variety of electrode configurations and preformed curves, but the most common catheters have either 4 or 10 electrodes for pacing and sensing. Steerable catheters have internal tension wires that allow the tip to be deflected up to 180 degrees or more by manipulating a control at the handle. Diagnostic steerable catheters may contain up to 20 electrodes. Catheters used for radiofrequency ablation are all steerable and generally consist of a 3.5- to 10-mm electrode used for ablation and three proximal recording electrodes. A diagnostic EPS typically requires at least three catheter locations: in the high right atrium near the sinus node, at His bundle area across the superior tricuspid valve, and at the right ventricular apex. Depending on the type of study, additional catheters may be placed in the right ventricular outflow tract, CS, anterolateral right atrium, interatrial septum, left atrium, pulmonary veins, and left ventricle.

Accessing the left ventricular cavity is accomplished either via the mitral valve from transseptal left atrial catheterization or via retrograde aortic approach through the arterial system, typically the femoral artery. Although left ventricular catheterization is not a routine part of a diagnostic EPS, it may have importance in patients with ventricular tachycardia and accessory pathway-mediated tachycardia (atrioventricular reciprocating tachycardia). Detailed catheter mapping of the left ventricular endocardium may also have benefit in defining the myocardial substrate in patients with ventricular arrhythmias, depressed ventricular function, history of myocardial infarction, and congestive heart failure.

CARDIAC MAPPING TECHNIQUES

Understanding the mechanism of arrhythmia is vital, before targeting with ablation, to maximize the success of the procedure. Understanding the arrhythmia mechanism can often be achieved with EPS but can be further refined with the use of cardiac mapping techniques. Cardiac mapping allows the identification of temporal and spatial relationships of electrical potentials during atrial and ventricular arrhythmias. The focus of cardiac mapping is generally to identify the origin of a focal arrhythmia or a site of critical conduction for a reentrant arrhythmia. The most common approaches to mapping are simple activation mapping, pace mapping, and electroanatomic activation mapping.

Electrograms acquired during mapping techniques are either bipolar or unipolar. Bipolar electrograms reveal the local electrical activity of the heart between two designated electrodes on the catheter. This typically is over an interelectrode spacing ranging from 1 to 10 mm. Unipolar electrograms reveal the local electrical activity at a single catheter point (usually the distal tip) relative to an electrode placed at a distance from the heart. The advantages of using unipolar mapping are that it gives a more precise measure of local activation and it provides information about the direction of impulse propagation. The advantages of using bipolar mapping include superior signal-to-noise ratio and less contribution from distant electrical activity ("far-field" activity). Frequently,

accurate mapping involves using both bipolar and unipolar electrograms at different points of the study.

Simple activation mapping is achieved by moving a single roving mapping catheter to various points of interest during an arrhythmia, spontaneous or induced, while measuring local activation times relative to a fiducial marker at a second site, such as the onset of the P wave or QRS complex or a stable intracardiac electrogram. Depending on the arrhythmia mechanism, the area of earliest activation is often a reasonable target for ablation of the arrhythmia.

Pace mapping is a mapping technique that can be used when the patient is not in the arrhythmia.¹ It is often used in conjunction with activation mapping as a second confirmatory test to determine the accuracy of the selected site for ablation, but it can be used as a stand-alone mapping technique if the documented clinical arrhythmia cannot be induced during EPS or is not hemodynamically tolerated. Pace mapping entails pacing the suspected target area for ablation at a rate similar to the clinical arrhythmia, and comparing the 12-lead electrocardiogram (ECG) to the ECG of the arrhythmia. A good pace map will have an exact match in 12 out of 12 leads; however, this is often difficult to achieve. When only minor differences in the ECG configuration and amplitude are noted, the spatial resolution of pace mapping can be as good as 5 mm. However, if only assessing for major differences in the 12-lead ECGs, special resolution may be as poor as 15 mm.² In addition to the 12-lead ECG, pace mapping also compares the intracardiac activation sequence seen on the electrophysiology catheters with the sequence observed during the arrhythmia if present or inducible.

Electroanatomic activation mapping relies on the use of specialized three-dimensional electroanatomic systems to assist with intracardiac mapping. The use of these systems can greatly reduce the amount of fluoroscopy time required for a procedure. Most commonly used are the CARTO 3 system (Biosense Webster) and the EnSite NavX system (St. Jude Medical) although the technology of cardiac mapping continues to evolve and newer mapping systems are currently in development. The CARTO 3 mapping system allows three-dimensional electroanatomic mapping using a low-intensity magnetic field and current-based visualization data to provide localization of multiple catheter tips and curves. The system can visualize up to five catheters with and without magnetic sensors but requires the use of compatible Biosense Webster catheters with magnetic sensors for electroanatomic mapping. Biosense Webster mapping catheters have miniature magnetic field sensors at the tip of the catheters, which can determine the location and orientation of the catheter within the magnetic field. With this information, one can create a three-dimensional reconstruction of cardiac chamber geometry. Isochromes of electrical activity can then be overlaid onto this geometry to help define reentrant circuits as well as localize the origin of focal arrhythmias. Additionally, voltage mapping can be performed in sinus rhythm to better delineate the underlying myocardial substrate in any chamber in question. The system has been shown to be highly accurate and reproducible in vitro and in vivo.³

The EnSite NavX mapping system also allows for three-dimensional localization of an intracardiac catheter through the use of three pairs of skin patches that send three independent, alternating, low-power currents through a patient's chest, each with a slightly different frequency. These currents can then be used to calculate different levels of impedances in all three planes corresponding to specific anatomic locations within the chest. Mapping catheter electrodes can then be used to measure different levels of impedance corresponding to specific locations in the heart as they are manipulated within the cardiac chambers. Using these calculated impedance coordinates, the system allows for real-time visualization of the position and motion of up to 64 different electrodes on the ablation catheter as well as other standard intracardiac catheters.⁴ Like CARTO 3, EnSite NavX can create three-dimensional geography of cardiac chambers and superimpose activation isochromes while mapping an arrhythmia or voltage measurements taken during sinus rhythm. However, unlike the CARTO 3 system, the EnSite NavX system does not require proprietary catheters for localization and mapping. EnSite also offers a noncontact mapping option using a 64-pole balloon catheter that generates mathematically derived electrograms and places them on a map of a cardiac chamber defined by a second, roving contact catheter.^{5,6}

CATHETER ABLATION

Catheter-based ablation techniques have been so successful in treating a variety of arrhythmias that they have virtually replaced surgical approaches. In catheter-based ablation, energy is delivered to a precise area of the heart. This is most often performed on the endocardial surface of the heart, although epicardial ablation is possible percutaneously via the subxiphoid approach and is performed routinely at many centers.^{7,8} After mapping techniques are used to identify the area or areas to be targeted for ablation, an ablation catheter is positioned in the desired location and connected to an energy source. Radiofrequency (RF) energy is the modality most commonly used clinically, having replaced direct current (DC) ablation because of superior safety and efficacy. Freezing the target area of the heart through a catheter-based cryoablation system is another method that can be used and is most commonly used in pediatric patients and in ablations performed adjacent to the intrinsic conduction system although cryoablation for atrial fibrillation using a cryoballoon catheter is becoming more common.

RF current is typically delivered in a unipolar configuration from the distal tip of the ablation catheter to a cutaneous grounding patch. The energy is generated as an alternating current with a frequency of 300 to 750 kHz.⁹ These frequencies produce effective heating with negligible muscle stimulation. During RF ablation, the electrical energy is converted to thermal energy by resistive heating. Most of the heating is concentrated at the tip of the catheter secondary to the small surface area of the tip relative to the cutaneous patch. The heat that is generated is transferred to the adjacent cardiac tissue primarily by conduction and to a lesser extent by

radiation, which decreases by the fourth power of the distance from the catheter tip. At steady state the RF lesion size is proportional to the temperature measured at the tissue-catheter interface, as well as proportional to the RF power amplitude.¹⁰

RF ablation results in thermal injury with coagulation necrosis when tissue heating exceeds approximately 50°C for at least 10 seconds.⁹⁻¹² As heat is produced at the catheter-myocardial interface, the impedance drops. A drop of 5 to 10 Ω is a sign of conductive heating to the adjacent tissue. The time to electrophysiologic effect after onset of RF current delivery is often shorter than one would anticipate for a pure thermal mechanism based on the documented rate of tissue temperature rise contiguous to the electrode. This raises the possibility that there is a contribution of a direct electrical effect in addition to the thermal effect of RF.

RF lesion size and power delivery are limited by tissue heating at the catheter-tissue interface on the endocardium. Newer ablation systems use external or internal saline irrigation to cool the catheter tip, which allows greater power delivery and the creation of deeper and larger lesions.¹³ The formation of coagulum may also be decreased with these systems. The catheters typically infuse saline either in a closed system running to the catheter tip or in an open system in which saline flows out small holes at the catheter tip at 17 to 30 mL/min during ablation, similar to irrigated surgical RF ablation devices. Externally irrigated ablation catheters have become the most common catheter used for ablation procedures for the treatment of ventricular tachycardia and atrial fibrillation.^{14,15}

Cryoablation has been used in the surgical treatment of arrhythmias for more than 20 years. Near-transmural lesions can be produced intraoperatively at temperatures of -60°C in the presence of cold cardioplegia. The blood pool presents catheter-based cryoablation systems with a major impediment in achieving adequate temperature. However, a catheter-based closed coolant system has been developed and is in clinical use. The major advantage is the ability to induce a nonpermanent change in tissue conduction, referred to as "ice mapping," followed by a permanent lesion if the ice mapping reveals a desirable location. This method has been used surgically with temperatures of approximately 0°C producing transient loss of electrical function and -60°C producing irreversible damage.¹⁶ A percutaneous approach is complicated by the warming effect of the circulating blood pool, and mean temperatures of -27°C were needed to achieve transient altering of electrical function.¹⁷ However, the temperature required for irreversible damage was similar to that needed in surgery (-58°C). Cryoablation catheters are most commonly used in the pediatric population and in ablations performed near the intrinsic conduction system where the risk of developing complete heart block is elevated. More recently, a cryoablation balloon has been developed which is capable of delivering a circumferential cryoablation lesion at the antrum of the pulmonary veins. This technology has been shown to reduce procedure times for pulmonary vein isolation with similar efficacy and adverse events compared with standard RF ablation.¹⁸⁻²⁰

SPECIFIC ARRHYTHMIAS

Atrioventricular Nodal Reentrant Tachycardia

Atrioventricular nodal reentrant tachycardia (AVNRT) is the most common form of supraventricular tachycardia.^{21,22} Medically, this arrhythmia is often treated with atrioventricular (AV) nodal blocking agents as well as occasionally with antiarrhythmic agents. The ability to cure this arrhythmia with a safe, well tolerated, and highly efficacious catheter ablation has made this a viable option for first-line therapy of AVNRT.²³

The AV node lies within the triangle of Koch, an area confined by the septal leaflet of the tricuspid valve inferiorly, the tendon of Todaro superiorly, and the CS os posteriorly.²⁴ In 1956, Moe and colleagues described physiologic evidence for a dual AV nodal pathway system.²⁵ These pathways were termed “slow” and “fast” based on their conduction time. However, there are no specific anatomic pathways that have been described that correlate with the fast and slow pathways. The functional dissociation of AV conduction into fast and slow pathways provides the substrate most often associated with AVNRT. The fast pathway normally lies at the apex of the triangle of Koch and the slow pathway at the base, near the CS os. However, there is often heterogeneity of atrial activation and these locations are not universal.

“Typical” or “common” AVNRT is usually initiated when a premature atrial impulse blocks in the fast pathway, conducts antegrade over the slow pathway, and then reenters the fast pathway in the retrograde direction (Fig. 86-1). This “slow-fast” AVNRT is responsible for approximately 90% of cases. The “atypical” or

“uncommon” form of AVNRT uses the slow pathway retrograde and fast pathway antegrade. Uncommonly, two relatively slow pathways constitute the reentry circuit (“slow-slow”). Although the terms “slow-fast,” “fast-slow,” and “slow-slow” are commonly used, attempting to classify all AVNRT into these groups is overly simplistic and incomplete given the complexity of AV nodal physiology and the lack of true discrete pathways in its structure.

Initial catheter ablation of AVNRT targeted the fast pathway region in the anterior interatrial septum.²⁶ Ablation at the apex of the triangle of Koch in the region of the fast pathway was more than 90% successful, but it carried an unacceptably high risk of AV block (5% to 10%). Ablation of the slow pathway²⁷ is accomplished via a posterior approach, with the ablation catheter initially positioned near the CS os, at the base of the triangle of Koch (see Fig. 86-1). RF current in the slow pathway region is often accompanied by transient accelerated junctional rhythm with rapid retrograde atrial conduction. This rhythm serves as a marker of a potentially successful ablation. However, rapid junctional tachycardia can be a marker for complete heart block, and ablation should be halted if it is seen.²⁸ Energy delivery should also be stopped if AV block or junctional rhythm with retrograde block is seen. Ablation is performed under continuous fluoroscopic monitoring or three-dimensional electroanatomic mapping to ensure catheter stability. In approximately 40% of cases, dual pathways are still present after ablation, but sustained ANVRT cannot be induced. Single AV nodal complexes (“echo beats”) are observed in three fourths of these patients with dual pathways post ablation, with block always occurring antegradely in the slow pathway. The success rate using a slow

FIGURE 86-1 ■ Mechanism of atrioventricular (AV) nodal reentry. The AV node is shown with two functional pathways: the slow and the fast. The anatomic locations of these pathways are debated and may vary among patients, but their common location is in the triangle of Koch. **A**, During sinus rhythm, the PR interval is short, and conduction occurs down the fast pathway. **B**, A late atrial premature contraction (APC) blocks in the fast pathway and conducts down the slow pathway to the ventricle, resulting in a longer PR interval. The fast pathway recovers the ability to conduct, and retrograde conduction occurs up to the atrium, resulting in an AV nodal echo beat. The slow pathway is refractory, however, so tachycardia does not occur. **C**, A critically timed APC causes more delay in the slow pathway, allowing retrograde conduction up the fast pathway and sequential activation over the slow pathway to initiate typical AV nodal reentrant tachycardia (AVNRT). CS, Coronary sinus; HB, His bundle; SP, slow pathway; TA, tricuspid annulus; TT, tendon of Todaro.

pathway approach is in excess of 95%.²⁹ Slow pathway ablation is preferred to fast pathway because of the equivalent success rate and the much lower risk of complete heart block (1% to 2%).

Atrial Tachycardia

Atrial tachycardias in patients who have never had an ablation or cardiac surgery are usually focal arrhythmias originating in the left or right atria with rates of 100 to 220 beats/min. The mechanism of atrial tachycardias may be automatic or triggered from focal sites or may be microreentrant involving a small area of atrial myocardium. Atrial tachycardias that are incessant and are caused by abnormal automaticity or triggered activity are most amenable to ablation and tend to be resistant to drug therapy.³⁰ Microreentrant atrial tachycardias are frequently easily managed pharmacologically, making ablation second-line therapy. Macroreentrant atrial tachycardias are commonly seen after atrial fibrillation ablation procedures or after cardiac surgeries using atriotomies. These macroreentrant arrhythmias are more common in such scenarios because scarring from previous procedures provides areas of functional block and slow conduction necessary for the initiation of reentry.

Incessant focal atrial tachycardias can occur from various locations in the heart but seem to have a propensity for the crista terminalis, both atrial appendages, the CS, the regions of the mitral and tricuspid annuli, and the pulmonary veins. It is unclear why these structures are prone to develop these rhythms. It has been postulated that regions such as the crista terminalis are sources of automatic atrial tachycardias because of relatively poor cell-to-cell coupling.³¹ Fractionated electrograms at successful ablation sites may be markers of a nonuniform anisotropic substrate because of poor coupling that allows focal automaticity to occur. In adults, atrial tachycardia foci are somewhat more common in the right atrium, and multiple foci are present in 10% to 15% of patients.

Because most incessant atrial tachycardias are focal in origin, the goal of catheter mapping is to find the earliest site of activation (Fig. 86-2). If the tachycardia is not incessant, catecholamine infusion, such as isoproterenol 1 to 10 $\mu\text{g}/\text{min}$ IV or atropine 0.5 to 1.0 mg IV, may be necessary to induce sustained arrhythmia. The initial localization of the arrhythmia focus is made by analysis of the P wave morphology and axis. Catheter mapping is then performed by identifying the site of earliest atrial activation relative to the onset of the P wave. Three-dimensional electroanatomic mapping systems (described earlier) are often used to aid in mapping the atrial activation sequence during tachycardia (Fig. 86-3). Once the catheter is positioned at what appears to be the earliest site of atrial activation, further evidence that it is the correct site of origin can be obtained by pace mapping. In this setting, pace mapping involves pacing at the earliest intracardiac site and comparing the resultant paced P wave morphology with the tachycardia P wave morphology, as well as comparing the sequence of intracardiac atrial activation during pacing and during the tachycardia.³² Pacing with higher output at the proposed site of ablation also helps confirm minimal risk of injury to the

FIGURE 86-2 ■ Ablation of atrial tachycardia. Atrial tachycardia is present. The ablation/mapping catheter is placed at the earliest electrogram recorded on a 64-pole basket catheter (vertical arrow). Radiofrequency (RF) energy delivered at this site terminates the tachycardia. Surface electrocardiogram leads I, aVF, V₁, and V₆ are shown. Map is the ablation catheter signal, and the letters F, G, and H refer to electrodes on the 64-pole basket catheter.

FIGURE 86-3 ■ Three-dimensional electroanatomic activation map depicting a focal atrial tachycardia. Maps of the right atrium (RA) and left atrium (LA) were created using point-by-point mapping with the CARTO system (see text). The color scale at the upper right represents the intracardiac activation timing at each point relative to a fixed reference in the coronary sinus. Red areas are earlier and purple areas are activated latest. Mapping of both the right and the left atrium revealed that the tachycardia was a focal atrial tachycardia originating anterior in the left atrium, near the aortic valve–mitral valve continuity. Ablation at this site successfully terminated the tachycardia. CS, Coronary sinus; LIPV, left inferior pulmonary vein; LSPV, left superior pulmonary vein; RSPV, right superior pulmonary vein.

surrounding extracardiac structures. This is particularly important in the right atrium with the proximity of the phrenic nerve; however, left phrenic nerve damage has also been reported with ablation in the left atrium.³³ Pacing that results in diaphragmatic stimulation would preclude ablation at that site.

The success rate of atrial tachycardia ablation is variable. For incessant tachyarrhythmias, the success rate approaches 90%, although the recurrence rate may be as high as 25%.^{32,34-36} Because the arrhythmia may not be reliably present or inducible at EPS (factors such as conscious sedation may serve to make them less inducible), a true success rate on an intention-to-treat basis is lower than 90%.

Sinoatrial node reentrant tachycardia represents a distinct entity within the category of atrial tachycardias. Criteria for the diagnosis are consistent atrial activation sequence and P wave morphology in sinus rhythm and tachycardia, consistent initiation and termination with programmed electrical stimulation, and termination of tachycardia with vagal maneuvers or with adenosine.³⁷⁻³⁹ Catheter ablation can be accomplished with good results and a paucity of complications, typically by ablating in the high posterolateral region of the right atrium at the "tail" of the sinus node.⁴⁰ Macroreentrant atrial tachycardias most often arise from the left atrium although they can also be seen in the right atrium. In the right atrium, the most common boundaries used for reentry aside from the cavotricuspid isthmus (discussed in detail in the atrial flutter section) include the CS ostium, the fossa ovalis, or scars from prior surgical incisions. In the left atrium, many left atrial tachycardias circulate around the mitral annulus with the pulmonary veins and the fossa ovalis as posterior boundaries.⁴¹ Scars from prior surgical or ablation procedures can also provide obstacles that lead to atrial tachycardias with large excitable gaps. In macroreentrant atrial tachycardias, electroanatomic mapping systems are often used to identify the macroreentrant circuit, anatomic or functional barriers used by the arrhythmia, gaps in regions of scar, and areas of slow conduction. Successful ablation of macroreentrant arrhythmias may be focal if targeting critical areas of slow conduction or gaps along areas of scar. However, in the case of large anatomic barriers or scars, lines of RF lesions may be required to connect anatomic barriers or scars to one another to interrupt the reentrant circuit.⁴²

Atrial Flutter

Atrial flutter is a rapid atrial arrhythmia with a rate faster than 220 beats/min. Typical isthmus-dependent atrial flutter is a macroreentrant circuit involving the right atrium. The posterior barrier of the circuit is formed by the crista terminalis and its continuation as the eustachian ridge.⁴³ The anterior barrier in typical flutter is the tricuspid annulus.⁴⁴ Typical atrial flutter is either counterclockwise or clockwise, depending on the direction of rotation in the frontal plane around the tricuspid annulus. Although counterclockwise flutter is the more common clinical entity, clockwise flutter can be initiated in most patients with typical atrial flutter.⁴⁵

The 12-lead ECG can give clues to the mechanism of the atrial flutter but sometimes can be ambiguous or misleading. Counterclockwise flutter is characterized by a predominantly negative, sawtooth-like atrial pattern in the inferior leads, with positive atrial deflections in lead V₁ and negative deflections in lead V₆. Clockwise flutter is characterized by a predominantly positive, notched

atrial pattern in the inferior lead, with negative atrial deflections in lead V₁ and positive deflections in lead V₆.

The term *atypical atrial flutter* is generally used to describe an arrhythmia with flutter waves on the 12-lead ECG felt to be inconsistent with an isthmus dependent arrhythmia. However, as noted earlier, the 12-lead ECG can be misleading in the case of atrial flutter, and it is not uncommon to identify an arrhythmia as isthmus-dependent atrial flutter at the time of EPS that terminates with ablation in the cavotricuspid isthmus, despite a 12-lead ECG inconsistent with the classic 12-lead ECG findings described earlier. If an atrial flutter is shown to be non-isthmus dependent, despite the lack of an obvious isoelectric interval on 12-lead ECG, a more appropriate classification would be macroreentrant atrial tachycardia. Further complicating matters, other macroreentrant right atrial tachycardias may have an appearance consistent with typical atrial flutter on surface ECG but may not rely on the cavotricuspid isthmus for reentry. For example, a reentrant circuit around the CS os (termed *intraisthmus reentry*) may have a 12-lead ECG appearance consistent with typical atrial flutter, but it requires a more medial cavotricuspid isthmus ablation beginning anterior to the CS os to facilitate termination.

In a catheter ablation procedure for typical atrial flutter, multielectrode catheters are placed in the CS and in the anterolateral right atrium, around a portion of the tricuspid annulus anterior to the crista terminalis. The catheter around the tricuspid annulus can help determine the direction of rotation, with atrial activation craniocaudal in counterclockwise flutter and caudocranial in clockwise flutter.

Catheter ablation of atrial flutter is dependent on the ability to interrupt the macroreentrant circuit at a critical narrow portion between barriers to conduction, termed the *isthmus*. In both counterclockwise and clockwise flutter, the isthmus targeted for ablation lies anterior to the inferior vena cava (IVC) and eustachian ridge, and posterior to the tricuspid annulus. During flutter, this isthmus is a zone of slow conduction.⁴⁶ Pacing from within this area slightly faster than the tachycardia will help demonstrate if the flutter uses this critical isthmus (i.e., isthmus dependent). If pacing in the isthmus at a rate slightly faster than the tachycardia entrains the tachycardia without alteration of the surface ECG flutter wave morphology and the local post-pacing interval equals the tachycardia cycle length, the tachycardia can be termed *isthmus dependent*. This pacing maneuver proves that the isthmus is a part of the atrial flutter circuit and that ablation in this area will effectively terminate the tachycardia.

Ablation of isthmus-dependent atrial flutter consists of creating a line of block across the right atrial cavotricuspid isthmus. Although this has been described for connecting the CS os to the tricuspid annulus, this approach can be prone to failure because of slow conduction through the eustachian ridge, which is not necessarily a fixed obstacle that produces block.⁴⁷ This can lead to a lower loop of reentry around the IVC, which meets the flutter loop going around the tricuspid annulus in a figure-of-eight manner.⁴⁸ Ablation between the tricuspid annulus and the IVC will eliminate lower loop reentry as

well as isthmus-dependent flutter and is the preferred ablation method.

Ablation is usually performed during atrial flutter. If flutter is not present at baseline, it can be induced with one or two atrial extrastimuli and/or rapid atrial pacing in 90% of atrial flutter patients and 95% of patients with isthmus-dependent flutter.⁴² Ablation can also be performed during pacing from the CS if the patient is not in atrial flutter at the time of the procedure. In patients in flutter, the arrhythmia is typically terminated during RF application in the isthmus; however, termination does not necessarily mean that the line of block is complete. Lack of complete isthmus block has been described in over 50% of cases when RF energy terminates flutter.³¹ To increase the success of the procedure, bidirectional block must be demonstrated.⁴⁹⁻⁵¹ This is demonstrated by pacing the CS catheter, which is medial to the line of isthmus block. When the ablation line is complete, there is no clockwise propagation through the isthmus, and activation is around the tricuspid annulus in a counterclockwise direction. This is seen on the tricuspid annulus catheter as craniocaudal activation during CS pacing. To verify the bidirectional nature of the block, pacing is performed from the lateral tricuspid annulus, lateral to the line of isthmus block. If the line of block is complete, there is no counterclockwise propagation through the isthmus, and activation is around the tricuspid annulus in a clockwise direction. In addition to bidirectional block, at the conclusion of the procedure, split atrial potentials (>100 ms apart) or absence of atrial potentials (electrograms <0.05 mV) may be seen along the ablation line. If bidirectional block is demonstrated, the incidence of atrial flutter recurrence is less than 10%.⁴²

Accessory Pathway–Mediated Tachycardia

Accessory AV connections (“accessory pathways,” “bypass tracts”) are part of a group of physiologic connections producing preexcitation syndromes. This group includes AV connections and nodoventricular, nodofascicular, atriofascicular, and fasciculoventricular connections.⁵²⁻⁵⁴ These pathways appear to represent developmental abnormalities, and it is not surprising that multiple types of accessory pathways may exist in any one patient. AV connections are responsible for the classic Wolff-Parkinson-White syndrome, which is defined as preexcitation seen on an ECG and the presence of an arrhythmia. These connections can conduct antegradely, leading to a preexcited ECG, whereas some may be “concealed” and only conduct retrogradely, from the ventricle to the atrium.

The clinical tachycardia most frequently associated with accessory AV pathways is atrioventricular reciprocating tachycardia (AVRT, or “circus movement tachycardia”). AVRT can be either orthodromic or antidromic. Orthodromic tachycardia results from antegrade conduction down the AV node and retrograde conduction up the accessory pathway. Antidromic tachycardia uses the same circuit but in the opposite direction.

The initial step in an ablation procedure is careful inspection of the 12-lead ECG. Determining the site of

TABLE 86-1 Localizing Accessory Pathways Using ECG Criteria

AP Location (Anatomic Description)	ECG Characteristics of Delta Wave
Left lateral <i>Posterior*</i>	Negative delta waves in leads I and aVL, and positive in inferior leads and precordial leads
Left posterior free wall <i>Inferoposterior</i> <i>Posteroseptal</i> <i>Inferoparaseptal</i>	Positive delta waves in lead I, negative in inferior leads, and positive in right precordial leads Positive delta wave in leads I and aVL and negative in inferior leads (although lead II may be isoelectric or biphasic, the more negative the more leftward the location)
Right free wall <i>Anterior</i>	Negative delta waves in leads V ₁ and V ₂ , positive in I and II, and slightly negative in III
Anteroseptal <i>Superoparaseptal</i>	Positive delta wave in lead I, positive in inferior leads (with lead II greater than III), and precordial leads with primarily negative or biphasic delta waves

*Newer anatomic descriptions for accessory pathway locations are in italics.

AP, Accessory pathway; ECG, electrocardiogram.

an accessory pathway requires either manifest preexcitation (i.e., presence of a delta wave) on the ECG or visible retrograde P waves during orthodromic AVRT. Although complex schema have been proposed, a simpler approach is most prudent because of variability in degree of preexcitation, variability in precordial lead placement, and variations in body shape/size, heart size, and position in the chest.⁵⁵⁻⁵⁸ This approach divides the location of accessory pathways into five regions: anteroseptal, right free wall, posteroseptal, left posterior free wall, and left lateral free wall. Full description of our approach to localizing pathways based on 12-lead ECG is well described elsewhere⁴² and is summarized in Table 86-1. Newer anatomic designations of accessory pathway locations are also provided in this table.⁵⁹

In the past, cardiac surgery was the only option for definitive treatment of accessory pathway–mediated tachycardias, but catheter ablation has replaced surgery as the preferred therapy over the past 20 years. In a catheter ablation procedure, a CS catheter is advanced to the anterolateral mitral annulus to permit mapping of all left-sided pathways except possibly the most anterolateral pathways, and additional catheters are placed in the right atrium and ventricle and adjacent to the His bundle.

Left-sided accessory pathways can use either a transseptal approach or a retrograde aortic approach. Atrial pacing is performed to elicit maximal preexcitation, and the location of the earliest ventricular activation along the CS is noted as the ventricular insertion of the pathway. To identify the atrial insertion, retrograde conduction over the pathway is mapped during ventricular pacing or, preferably, during circus movement tachycardia (to ensure no contribution of retrograde AV nodal conduction), with the site of earliest atrial activation identifying

the atrial insertion. It is important to identify both atrial and ventricular insertions of any accessory pathway when possible, given that slanted pathways are common and ablation at an insertion site may not adequately target the pathway itself. In the setting of concealed pathways, only the atrial insertion can be mapped, although other maneuvers can be used to assess for the presence of a slanted pathway.⁴² If retrograde conduction over the pathway is intermittent or tenuous during the resting sedated state of EPS, isoproterenol can be administered. This can also facilitate initiation of circus movement tachycardia. If rapid retrograde conduction over the AV node during ventricular pacing makes localization difficult, verapamil can be administered to facilitate conduction over the pathway.

After mapping of the accessory pathway, a steerable ablation catheter is then advanced to a position near the accessory pathway. The ventricular insertion of the pathway is best approached via the retrograde aortic approach, whereas the transeptal approach allows easiest access to the atrial insertion site. Success rates of initial attempts at ablation appear to be similar in either approach.⁶⁰ Ablation should target the area between the atrial and ventricular insertions when both can be identified, which is generally near the site of the earliest ventricular activation in manifest pathways and the earliest atrial activation in concealed pathways as the shortest AV and ventriculoatrial (VA) intervals may not be the best target for ablation in slanted pathways. Electrograms recorded at insertion sites of pathways are often fractionated, and occasionally a bypass tract potential can be recorded.

Factors that predict a successful ablation site for a pathway include a stable electrogram, catheter stability and catheter motion in conjunction with the CS catheter, presence of an accessory pathway potential, catheter position at the shortest recorded AV interval (or shortest VA interval if concealed), and activation of the local ventricular electrogram before the onset of the QRS if it is a manifest pathway.

The mapping of right-sided pathways uses similar principles to those used for left-sided pathways. An atrial approach is most commonly used for right-sided accessory pathways. Right atrial pathway ablation can be more complicated because of (1) the presence of a "sack" of atrial myocardium folding over the tricuspid AV ring, which makes catheter manipulation more difficult; (2) possible circumferential tricuspid pathway location versus only approximately 75% of the mitral annulus because of lack of pathways in the region of aortomitral continuity; and (3) lack of an AV groove reference catheter. A multipolar halo catheter can be positioned around the tricuspid annulus to serve as an AV groove reference, but positioning may not always be accurate as it can be difficult to place in a true annular position. When endocardial ablation fails to eliminate accessory pathway conduction, epicardial mapping and ablation can be performed with percutaneous access to the pericardial space.⁶¹ In this procedure, via a subxiphoid approach, a standard sheath is advanced over a wire into the pericardial space and an ablation catheter is manipulated under fluoroscopic guidance for epicardial mapping.⁶²

FIGURE 86-4 ■ Ablation in Wolff-Parkinson-White syndrome. Electrocardiogram leads I, aVF, V₁, and V₆ and proximal (CS 9,10) to distal (CS 1,2), and RV apical (RVA) recordings are shown. The bypass tract is a left posterior bypass tract. Radio-frequency (RF) energy produces loss of the delta (δ) wave in 4 seconds (see text).

Coronary angiography is usually required before ablation to ensure ablation is not performed over large epicardial arteries. Pericardial scarring often prohibits this approach in patients who have had cardiac surgery.

After adequately localizing the accessory pathway, RF current is delivered through the distal electrode of the ablation catheter. Successful ablation typically results in loss of accessory pathway conduction within 10 seconds (Fig. 86-4). The patient is then monitored for at least 20 minutes to watch for resumption of accessory pathway conduction, often in the presence of isoproterenol given intravenously. The success rate for catheter ablation of all accessory pathways is greater than 90%.⁶³

Reentrant Ventricular Tachycardia and Structural Heart Disease

Most sustained monomorphic ventricular tachycardia (VT) seen clinically is in patients with coronary artery disease and is most frequently the result of scarred myocardial substrate from a prior myocardial infarction (MI). In this setting, the primary mechanism for VT is reentry. Reentrant circuits are prone to develop secondary to fibrosis from the prior infarction causing disruptions in cellular coupling leading to abnormal paths of conduction as well as zones of slow conduction. Surgical subendocardial resection of these areas has proven curative in selected patients. With the advent of catheter ablation, surgical ablation for VT fell out of favor because of unacceptably high morbidity and mortality rates.⁶⁴⁻⁶⁷ However, these high mortality rates are from surgical series in the 1980s, and one might expect these numbers to be lower today with improved myocardial preservation techniques and additional methods to facilitate the procedure. Thus, surgical therapy for ventricular arrhythmias, particularly in conjunction with coronary artery bypass grafting surgery, is almost certainly an underused procedure

today. Nevertheless, catheter-based VT ablation has supplanted surgical treatment in most cases.

Patients with structural heart disease but no known coronary artery disease or prior MI (such as arrhythmogenic right ventricular cardiomyopathy, hypertrophic cardiomyopathy, or non-infarct-related cardiomyopathy) can also present with sustained monomorphic VT related to reentry. As is the case with prior MI, the pathophysiology is generally related to underlying scar and fibrosis. For the purposes of this section, we focus on mapping and ablation of sustained monomorphic VT in the setting of infarct-related cardiomyopathy. However, the approach to mapping and ablation of non-infarct-related VT is generally similar although the most common areas of fibrosis tend to be different, being more often perivalvular or epicardial.

Approximately 95% of patients with a prior MI who present with sustained monomorphic VT will be able to have the clinical arrhythmia induced at EPS. Ideally, to be considered for ablation, the VT should be hemodynamically tolerated, which allows for careful ventricular mapping during the arrhythmia. Substrate mapping during sinus rhythm can identify scarred arrhythmogenic substrate in patients with hemodynamically intolerated VT or in patients in whom VT cannot be induced, which can then be modified with ablation. However, activation and entrainment mapping techniques require hemodynamically tolerated inducible VT. If the rapid rate of a VT is contributing to hemodynamic compromise, administration of agents such as procainamide can slow the VT enough to allow for adequate mapping during VT. Alternatively, vasopressors such as dopamine, norepinephrine, or phenylephrine may be administered to support the patient's blood pressure during an otherwise intolerated VT. A newer alternative involves use of a percutaneous ventricular assist device (pVAD) to maintain adequate perfusion in the setting of rapid VTs or advanced cardiomyopathy. The disadvantages of this strategy are complications inherent in the use of a highly invasive pVAD. However, the potential advantage is that it may allow for induction and mapping of VT, which would be suitable only for a substrate ablation in other circumstances. Further studies are required to determine whether this more invasive strategy translates to improved procedural success rates.^{68,69}

The "site of origin" of the VT is essentially the source of electrical activity producing the VT QRS. Although this is a discrete site in automatic and triggered rhythms, post-MI VT is typically a reentrant rhythm. During reentrant VT, the arrhythmia circuit involves normal myocardium and a protected "isthmus" of scarred myocardial tissue. Because of myocardial scarring and fibrosis, electrical conduction through the isthmus is slow, forming the diastolic interval in the tachycardia circuit.⁷⁰ This isthmus is identified as an area of low voltage on electroanatomic mapping with fractionated electrograms and diastolic potentials seen during tachycardia. The site of origin represents the exit site from the diastolic pathway to the myocardium giving rise to the QRS. The initial step in localization of the VT is examination of the ECG.⁷¹⁻⁷³ Approximately 59% of VTs can be localized with 93% accuracy. Left bundle branch block VT

morphology can be more accurately localized than can right bundle branch block morphology, and VT from a prior inferior MI can be more easily localized than VT from a prior anterior MI.^{42,71,72}

During EPS, once the clinical VT has been induced, an ablation catheter is advanced into the left ventricle after heparinization to an activated clotting time (ACT) of greater than 250 seconds. Either a transseptal or a retrograde aortic approach can be used. Further mapping of the VT is then performed by examination of the electrograms obtained during the VT, as well as their response to pacing during the VT. Stevenson and colleagues have devised a scheme to help understand the various components of the reentry circuit, including the central common pathway or protected isthmus of myocardium that is the target site for ablation.⁷⁰

Regardless of the approach to localizing the protected isthmus, the three major steps are as follows:

1. Activation mapping, consisting of finding the site of early activation closest to mid-diastole. These electrograms frequently are low-amplitude fractionated potentials.
2. Demonstration that this diastolic electrogram has a fixed relationship to the subsequent QRS despite pacing-induced oscillations in the VT cycle length.
3. Performing entrainment mapping to demonstrate an entrained QRS morphology identical to the VT morphology ("concealed entrainment"), with an activation pattern during pacing and after cessation of pacing proving that the site in question is part of the reentry circuit.

If all three criteria are met, there is a greater than 95% chance of terminating the VT with ablation at a single site in the protected isthmus (Fig. 86-5).⁷⁴

Entrainment mapping consists of ventricular pacing at a cycle length slightly shorter than the VT cycle length and seeing if the three previously listed criteria are met.^{70,74-78} Pace mapping, as described earlier for atrial tachycardia, is another method for localizing the VT circuit. In this technique, pacing is performed from candidate sites in the ventricle, and the 12-lead ECG is compared with the VT ECG. An identical match in all 12 leads is considered an ideal pace map. We do not advocate using pace mapping as a primary mapping modality for post-MI VT, however. A pace map that appears similar to the VT would only identify the exit point for the critical isthmus and may be distant from the common pathway ablation target. In addition, pacing during sinus rhythm activates the myocardium in both directions from a protected isthmus, whereas the QRS during reentrant VT is the result of unidirectional activation of the myocardium by the cyclical depolarization front.

When the clinical VT cannot be hemodynamically tolerated after being induced during EPS, consideration can be given to mapping and ablation during sinus rhythm. This technique is known as "substrate ablation" and is similar in principle to the intraoperative surgical ablation techniques used in some centers. Low-amplitude fractionated electrograms and late potentials have been demonstrated in areas of infarction using standard catheter techniques during sinus rhythm.⁷⁹ One study showed

FIGURE 86-5 ■ Mapping and ablation of ventricular tachycardia (VT). **A**, Electrocardiogram leads 1, 2, 3, aVF, V₁, and V₅ are shown during VT with electrograms from the right ventricular outflow tract (RVOT), the right ventricular apex (RVA), and the site of the earliest activity in the left ventricle (LV 4-6). Entrainment of VT from LV 4-6 produces a QRS identical to VT, a stimulus (STIM)-QRS identical to the electrogram to QRS (arrow). **B**, Radiofrequency (RF) application at this site terminates VT. CL, Cycle length; PCL, paced cycle length; RC, return cycle.

that although no specific electrogram characteristic could predict a VT site of origin with adequate specificity, 86% of VTs arose from areas with these abnormal electrograms. Another study showed that the number of abnormal electrograms in cardiac arrest patients (who more often have ventricular fibrillation or polymorphic VT) was smaller compared with the number of patients with sustained monomorphic VT.⁸⁰ Standard catheter techniques do not allow for precise three-dimensional localization of the abnormal electrograms. Endocardial voltage mapping using an electroanatomic mapping system such as CARTO (see earlier) in a chronic infarct model has been shown to more accurately delineate infarcted myocardium than can pathology.^{81,82} Clinically, voltage mapping is used to guide endocardial VT ablation by identifying areas of scar and potential areas of protected isthmuses.⁸¹ Using bipolar voltage mapping, normal endocardial bipolar electrogram voltage using electroanatomic mapping is defined as more than 1.5 mV, based on mapping of controls, and scar is defined as areas with low voltage, less than 0.5 mV. Linear ablation lesions are extended from areas of dense scar to areas of normal voltage myocardium or to anatomic boundaries such as the mitral valve, resulting in a 75% success rate in patients with drug refractory VT that was not hemodynamically tolerated during EPS (Fig. 86-6). A randomized trial showed that prophylactic substrate catheter ablation in patients with a history of VT or ventricular fibrillation was able to reduce the number of implantable cardioverter-defibrillator (ICD) shocks received by patients who had undergone ablation.⁸³ Although ICDs reduce mortality from ventricular arrhythmias, shocks are uncomfortable and are associated with increased subsequent mortality,⁸⁴ and therefore catheter ablation is often considered in patients with ICDs who have received shocks for VT.

Although less commonly performed than endocardial ablation, epicardial ablation of VT is possible both surgically and percutaneously via a subxiphoid approach for

FIGURE 86-6 ■ Substrate ablation of ventricular tachycardia. A three-dimensional electroanatomic CARTO map of the left ventricle is shown in a modified right anterior oblique orientation. The mitral valve (MV) and the septum and part of the anterior and inferior walls are shown. The colors represent electrogram voltage, shown on the scale (right) in a range from 0.1 mV to 0.5 mV. Purple areas are relatively normal myocardium, red areas represent dense scar (S), and between them are areas of viable myocardium with scar. Conduction is slow through these areas, and isthmus channels (IC) can be identified. Red dots represent ablation sites. Note that ablation lines (white lines) extend from areas of scar across the isthmus channel to adjacent areas of scar and from areas of scar to the mitral valve. Additional ablations were also created in the border zone (B) at areas with fractionated electrograms (see text). L, Left; R, right.

access of the pericardial space, often in conjunction with endocardial ablation. This approach is most often used for cardiomyopathies associated with VT of an epicardial origin (non-infarct-related cardiomyopathy, Chagas disease, etc.) or in patients who have refractory VT despite previous endocardial ablation attempts. In some

centers, epicardial ablation is used as a first-line ablation strategy for patients with VT.⁸⁵ Once epicardial access has been obtained, the process of mapping and ablation of VT is similar to that of the endocardial approach. However, catheter manipulation can be more challenging in the epicardium, and coronary angiography before the delivery of RF energy is important to ensure the ablation catheter is a safe distance from the large epicardial coronary arteries. In patients status post coronary artery bypass grafting, localization of bypass grafts is important in order to avoid laceration of grafts during catheter manipulation. Furthermore, in any patients with a history of prior open heart surgery, epicardial scarring and pericardial adhesions can make catheter manipulation in the epicardial space difficult if not impossible. Of note, epicardial ablation has also been used for arrhythmias other than VT, including inappropriate sinus tachycardia, refractory atrial arrhythmias despite previous endocardial ablation, and accessory pathways inaccessible from an endocardial approach.⁸

Idiopathic Ventricular Tachycardia

VT occurs most often in patients with underlying structural heart disease. VT is also seen in patients without known structural heart disease; this is known as idiopathic VT. The most common type of idiopathic VT is caused by triggered activity from delayed afterdepolarizations. It is typically catecholamine dependent, frequently brought on by exertion or emotional stress, and can be terminated by vagal maneuvers, adenosine, calcium channel blockers, or sodium channel blockers. The term *idiopathic VT* is a misnomer because patients with underlying structural disease can also have triggered, focal VTs arising from similar locations and behaving in similar ways to VTs seen in patients without structural disease. With this understanding, it is more appropriate to characterize all VTs based on tachycardia mechanism in addition to underlying substrate.^{85a} For the purposes of this section, we focus on the approach to triggered, focal VTs in patients without underlying structural disease, most commonly referred to as idiopathic VT. These tachycardias most commonly arise from the right ventricular outflow tract (RVOT),^{86,87} coronary cusps, left ventricular outflow tract (LVOT),^{88,89} and mitral annulus,⁹⁰ but have also been reported at other sites in the left and right ventricles.

The characteristic ECG for RVOT VT is a left bundle, inferior axis, with either a right or left axis depending on the location in the outflow tract. For LVOT/coronary cusp VT, the ECG typically has a small r wave in V₁ with early development of a large R wave in the right precordial leads and an inferior axis. These VTs often require catecholamine infusion during EPS for induction. The approach to mapping and ablation for both RVOT and LVOT/coronary cusp VTs is similar.⁹¹⁻⁹⁴ Activation mapping using both bipolar and unipolar electrograms followed by confirmatory pace mapping is the most reliable method for localizing the focal source of these tachycardias. An electroanatomic mapping system is often used to track the timing of catheter points to locate the earliest electrogram relative to the surface ECG and guide

ablation. In the absence of structural heart disease, pace mapping for focal idiopathic VT is a viable modality for localizing the site of origin, unlike in post-MI VT.⁹⁵ Ablation is performed at the earliest identifiable site of ventricular activation or at the site with a pace map identical to that of the clinical tachycardia.

A second and less common variety of idiopathic VT arises from the left ventricle, is reentrant, and is verapamil sensitive.^{93,94,96} The characteristic ECG is right bundle, superior axis, which can be left superior if it is coming from the posterior third of the septum or right superior if it is coming from the apical third. Opinions regarding the optimal approach to ablation vary, but activation mapping of the site of earliest ventricular activation along the septum, followed by pace mapping, is generally a reasonable approach. Some authors advocate targeting presystolic Purkinje potentials or mid-diastolic potentials.^{97,98} Electroanatomic activation mapping and identification of the earliest retrograde Purkinje potentials has also been used to guide ablation.⁹⁹ Entrainment mapping has been reported but is difficult to achieve. Ablation for this type of VT should use as many mapping modalities as possible, with consideration of the Purkinje spike, concealed entrainment if attainable, activation mapping, and confirmatory pace mapping.

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia encountered in clinical practice. Catheter ablation for treatment of AF was previously limited to ablation of the AV junction combined with pacemaker implantation in patients refractory to, or intolerant of, pharmacologic therapy. Over the past 15 years, catheter ablation has become a common strategy for decreasing the burden of AF in patients refractory to medical therapy, through elimination of AF triggers and modification of the atrial substrate responsible for the maintenance of AF.

Atrioventricular Junction Ablation

Ablation of the AV junction was the first use of catheter ablation and used DC energy; however, RF energy is superior and is now used for this procedure.^{100,101} This procedure is indicated for patients who have been unable to tolerate medical therapy for AF or in whom it has been ineffective and requires pacemaker implantation before ablation. To perform AV junction ablation, an ablation catheter is advanced beyond the superior aspect of the tricuspid valve, along the ventricular septum, until the maximum amplitude His bundle recording is observed. The catheter is then withdrawn 1 to 2 cm until a large atrial electrogram and occasionally a very small His bundle recording is seen. Ablation is performed in this region until AV block is achieved. This technique targets the distal portion of the AV node and allows for an intact junctional escape pacemaker to persist and provide backup heart rate in the case of pacemaker failure. Occasionally this approach fails and despite ablation of the distal AV node, rapid conduction persists. In these cases, ablation is performed over the His bundle region. In up to 10% of cases, ablation of the His bundle from the left

side is required to achieve effective AV block.¹⁰² After ablation, the patient is commonly monitored in the electrophysiology laboratory during isoproterenol infusion to assess for resumption of conduction. The success rate of this procedure for achieving AV block has been reported to be 97.4%.²⁹

Ablation of the AV junction has been associated with an increased risk of sudden cardiac death, thought to be caused by polymorphic VT related to electrical instability and changes in repolarization caused by the sudden change in heart rate and myocardial activation sequence.¹⁰³⁻¹⁰⁵ These changes may be manifest as QT prolongation and torsades de pointes. As a result, after AV junction ablation, the pacemaker is initially programmed to a lower pacing rate of 80 to 90 beats/min, which is then slowly decreased over several months at follow-up visits.

Catheter Ablation of Atrial Fibrillation

The role of catheter ablation of AF in the management of patients with AF continues to evolve. Haissaguerre and coworkers observed that focal triggers originating in the pulmonary veins may initiate AF; this led to a new catheter-based approach to the treatment of AF.¹⁰⁶ Early procedures used focused catheter ablation of ectopic foci found in pulmonary veins and had limited success. Researchers then proceeded to perform extensive ablation in the pulmonary veins, but this was complicated by pulmonary vein stenosis caused by scarring of the proximal veins.¹⁰⁷ Since that time, multiple newer techniques for isolating the pulmonary veins have been used.

Segmental ostial pulmonary vein isolation is based on the principle that pulmonary vein triggers initiate AF in the left atrium. Ablation is performed around the ostium of each pulmonary vein until conduction block at the left atrium-pulmonary vein border is achieved. The goal of this method is to electrically isolate each vein, thus preventing pulmonary vein triggers from reaching the left atrium to initiate and perpetuate AF.^{108,109} More recently, circumferential left atrial (LA) ablation and wide-area left atrial catheter ablation (WACA) have been used for the treatment of AF. This strategy uses creation of ablation lines that encircle the ostia of all four pulmonary veins, usually in two pairs, one around the left pulmonary veins and one around the right pulmonary veins. These ablation lesions are generally driven by anatomic landmarks and do not require detailed mapping of focal electrical connections between the pulmonary veins and the left atrium, which can simplify the procedure although a greater number of ablation lesions is usually required, resulting in longer procedural times. WACA results in more extensive ablation across a wider area of the left atrium compared with segmental ostial pulmonary vein isolation (PVI), which may provide additional means of preventing AF recurrence including autonomic denervation,¹¹⁰ elimination of AF triggers outside of the pulmonary veins,¹¹¹ and modification of the LA substrate that may facilitate perpetuation of AF.¹¹² In conjunction with ablation around the pulmonary veins, additional ablation lines may be created connecting ablation lines to one another or to anatomic landmarks, such as the mitral

annulus. These additional lines are intended to interrupt potential macroreentrant circuits that could otherwise lead to LA tachycardias.

Small randomized studies that compared segmental ostial PVI with circumferential LA ablation yielded conflicting results. One study found that rates of recurrent symptomatic paroxysmal AF were higher in the segmental ostial PVI group, whereas another study reported that symptomatic recurrences and atrial arrhythmias seen on ambulatory monitoring were significantly greater in the circumferential ablation group.^{113,114} Unfortunately the two studies are not directly comparable because of differences between patient populations and study design. Currently, most physicians believe that a circumferential or WACA approach is superior to a segmental ostial approach. However, there continue to be wide variations in practice patterns. An expert consensus statement recommends that electrical isolation should be the goal of ablation around the pulmonary veins.¹¹⁵ Electrophysiologic criteria for ablation success vary, but the most rigorous operators aim for elimination of electrical signals at the site of ablation and elimination of electrical conduction into the pulmonary veins from the left atrium (entrance block) and from the pulmonary veins to the left atrium (exit block).

Beyond electrical isolation of the pulmonary veins, additional focal ablation in the atria at a variety of different locations has become increasingly popular. It has been postulated that nonpulmonary venous structures entering the atria are alternative triggers of AF, and ablation of regions around the superior vena cava, ligament of Marshall, and CS are performed by many operators as adjunctive therapy to PVI.¹¹⁶ Complex fractionated atrial electrograms (CFAEs) have also been a target of ablation and extensive research. CFAEs are found mostly in areas of slow conduction and it has been postulated that they may be important components of the substrate that allows maintenance of AF. One study reported a high percentage of freedom from arrhythmia following CFAE ablation without PVI in paroxysmal AF patients.¹¹⁷ Beyond the CFAE debate, controversy also remains regarding the benefits of LA substrate modification with additional ablation lines beyond those created to isolate the pulmonary veins. The argument for the creation of additional lines is that RF lesions may create reentrant circuits. LA tachycardias appear to be more common after circumferential PVI as opposed to segmental ostial PVI, which may add weight to this argument because wider ablation lesions may facilitate development of macroreentry.¹¹³ However, an argument against the creation of additional lines is that LA tachycardia following PVI is often treated successfully with reisolation of the pulmonary veins without additional linear ablation lesions.^{117,118}

In practice, AF ablation is now often performed using a stepwise technique.¹¹⁹ Ablation around the pulmonary veins is first performed with the goal of electrical isolation of the veins. Although this technique is often adequate in patients with paroxysmal AF, patients with persistent or chronic AF often require further ablation. Guided by inducibility of AF and conversion of AF during ablation, additional linear lesions may be created. If the patient continues to have inducible AF or remains in AF,

some physicians choose to ablate areas of the left atrium exhibiting CFAEs during LA mapping.^{112,119}

Because catheter ablation of AF is invasive and has procedural risks, it is generally reserved for patients who do not respond to medical therapy with antiarrhythmic drugs.¹²⁰ With the low efficacy of medications and the high success rates of catheter ablation in experienced centers, this procedure is occasionally considered first-line therapy for patients who do not wish to take antiarrhythmic medication. A meta-analysis has demonstrated that the efficacy of catheter ablation is significantly greater than the efficacy of medical therapy.¹²¹ Reported success rates vary widely, ranging from 42% to 88% for patients with paroxysmal AF in studies with adequate follow-up available.^{113,122-124} Success rates for patients with persistent AF are much lower, reported at approximately 50% in most studies, and a recent study of long-standing persistent AF suggested a single procedure success rate as low as 20%.¹²⁵ The complication rate for this procedure is as high as 6%, with tamponade, pulmonary vein stenosis, stroke, and access site complications being the most common adverse outcomes.¹²³ The reasons for this relatively high complication rate include the use of multiple catheters, the transseptal puncture procedure, the need for high-intensity systemic anticoagulation, and the manipulation of catheters and creation of ablation lesions in the left atrium. The most recent American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines on the management of patients with AF make a strong recommendation for RF ablation for patients with symptomatic paroxysmal AF who have failed treatment with an antiarrhythmic drug and a weak recommendation for RF ablation for patients with symptomatic, persistent AF. They make a very weak recommendation for RF ablation for patients with symptomatic paroxysmal AF and significant LA dilation or significant left ventricular dysfunction.¹²⁰

Although specific techniques vary, most operators place standard electrophysiology catheters in the CS and right atrium. Transseptal puncture is then performed. This is accomplished using the standard technique developed 50 years ago.¹²⁶ A long sheath with an inner dilator designed for transseptal access is advanced to the right atrium and placed in the fossa ovalis. Location is confirmed using fluoroscopic landmarks, intracardiac ultrasound, and/or injection of a small amount of contrast dye to "stain" the septum (Fig. 86-7). When location at the fossa ovalis is confirmed, a long needle is advanced from the tip of the dilator until the septum is punctured. Entry into the LA is confirmed by injection of microbubbles seen on intracardiac ultrasound, injection of dye under fluoroscopy, advancement of a wire into the LA or pulmonary vein, and/or direct pressure measurement. Once LA access is achieved with one or two sheaths, an ablation catheter and circular mapping ("lasso") catheter are placed in the left atrium. Systemic anticoagulation with IV heparin is administered throughout LA access with activated clotting times kept between 250 and 400 seconds.

Once LA access is obtained, mapping of the left atrium and pulmonary veins is performed using a three-dimensional electroanatomic mapping system. Recent

FIGURE 86-7 ■ Intracardiac ultrasound image of transseptal catheterization. The transseptal sheath (S), fossa ovalis (FO), left atrium (LA), and left superior pulmonary vein (LSPV) ostium are shown. The typical "tenting" of the fossa ovalis by the transseptal needle advanced through the sheath confirms appropriate positioning of the needle for puncture of the fossa ovalis.

FIGURE 86-8 ■ Three-dimensional electroanatomic map of the left atrium showing integrated information from intracardiac mapping and a previously acquired computed tomography image (CartoMerge, Biosense Webster, Inc.). This patient has a left common pulmonary vein (LCPV) that gives rise to superior and inferior branches, and separate right-sided pulmonary veins. The red and gray circles indicate sites of ablation performed in a circumferential pattern around the pulmonary veins. Bidirectional electrical isolation of all pulmonary veins without additional ablation lines was performed in this patient. LAA, Left atrial appendage; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein.

advances in this technology have allowed the integration of previously acquired computed tomography or magnetic resonance imaging images or real-time tomographic fluoroscopy or intracardiac ultrasound images of the left atrium into the mapping system (Fig. 86-8). Ablation is then performed as described earlier. Manual catheter manipulation remains the most common method, but newer technologies allowing remote magnetic catheter guidance or robotic catheter guidance have been developed and are in limited clinical use.¹²⁷⁻¹²⁹ These technologies show promise for reducing radiation exposure to patient and operator and possibly increasing the safety of the procedure.

Cryoballoon Ablation of Atrial Fibrillation

As mentioned previously, a cryoballoon catheter has been specifically designed for the treatment of AF and is now in use worldwide. The goal of cryoablation for AF using the cryoballoon is electrical isolation of the pulmonary veins. In comparison to RF therapies for AF, cryoballoon functions most like circumferential pulmonary vein isolation: after balloon deployment, cryothermal energy is delivered at the pulmonary vein antrum but does not target other areas beyond the pulmonary veins. To facilitate cryoballoon ablation, a transseptal catheterization is performed using the technique described earlier. After obtaining LA access, a standard transseptal sheath must be upsized to a specialized 12 Fr steerable sheath designed specifically to deliver the cryoballoon, available in two different sizes. Just as with RF ablation, systemic anticoagulation with IV heparin is administered throughout LA access with activated clotting times kept between 250 and 400 seconds. Through the transseptal sheath, the cryoballoon is advanced to the LA and a specialized circumferential mapping ("lasso") catheter is advanced through the cryoballoon and into the targeted pulmonary vein. The cryoballoon is then inflated in the LA and advanced over the lasso catheter until it is positioned into the antrum of the pulmonary vein. Contrast dye is then injected into the pulmonary vein distal to the cryoballoon under fluoroscopy to assess for occlusion. Color Doppler on intracardiac ultrasound is now widely used to assess for pulmonary vein occlusion. Complete occlusion is considered a surrogate for circumferential contact with the cryoballoon. Cryothermal energy is then delivered through the cryoballoon, generally in two applications. Entrance and exit block is then assessed in the same manner as described earlier. Additional cryoballoon applications can be applied as needed. The process is repeated for all major pulmonary veins. If isolation cannot be achieved with the cryoballoon alone, focal ablations can be performed as needed with a cryoablation catheter or standard RF catheter.

The major advantages of cryoballoon ablation for AF are a decrease in procedure time and reduced risk of complications related to RF energy, specifically thrombus formation at the site of lesion creation and cardiac perforation caused by excessive heating or catheter-related trauma. Theoretically, the cryoballoon ablation is also less complex and less dependent on operator dexterity, which is required to create contiguous curvilinear lesions with focal RF ablation. Centers with extensive cryoballoon experience have reported a progressive decline in procedural times, which are generally shorter than average procedural times for RF ablation.¹⁹ Efficacy of cryoballoon ablation for paroxysmal AF has been shown to be similar to results reported for standard RF ablation in nonrandomized and randomized trials.^{18,20,130} For patients with persistent AF, cryoballoon ablation alone has yielded low 1-year procedural success rates, likely related to the knowledge that patients with persistent and permanent AF may require more extensive atrial ablation beyond the pulmonary vein antra to adequately modify their substrate for AF. Combined approaches using cryoballoon ablation and RF ablation for creation of linear

ablation lesions have reported better results in such patients.¹³¹

Complications of cryoballoon ablation appear to differ slightly from those of standard RF ablation. Tamponade and atrioesophageal fistulas have been reported less frequently in cryoballoon ablation. However, phrenic nerve paralysis has been reported with a significantly higher frequency compared with RF ablation, although for most patients, phrenic nerve paralysis is temporary and short-lived.^{19,20} Because of the frequency of this complication, routine use of high output phrenic nerve pacing in the superior vena cava with palpation of the diaphragm during energy application in the right pulmonary veins is routine practice. Pulmonary vein stenosis has also been reported with cryoballoon ablation although most patients were asymptomatic and stenosis was discovered as a result of aggressive postprocedure screening.²⁰

The optimal therapy for AF remains unclear and must be tailored to each patient. Structural heart disease, sleep apnea, aging, and fibrosis all make catheter ablation less likely to be successful. Combination therapy with antiarrhythmic drugs is often required. Many patients with long-standing AF, severe valvular disease, or severely dilated atria have a very low likelihood of success with catheter ablation, and in these patients a strategy of rate control of AF without aggressive attempts to restore sinus rhythm is often indicated. However, many other patients with AF benefit from pulmonary vein isolation with RF energy, cryoballoon ablation, or a combination of the two, and the use of these modalities has become widespread.

Conclusions

Current nonpharmacologic treatments for cardiac arrhythmias include catheter ablation, implantation of pacemakers and cardioverter-defibrillator devices, and surgery. These modalities can be used to treat essentially all supraventricular and ventricular tachyarrhythmias. Although the indications for surgical intervention have narrowed, surgery remains an important treatment option, especially for the most common of all arrhythmias, atrial fibrillation.

ATRIAL FIBRILLATION

Background

Atrial fibrillation (AF) is present in up to 2% of the general population and in approximately 10% of patients

older than 60 years, making it the most common form of sustained cardiac arrhythmia.¹⁻⁵ From 1993 to 2007 the prevalence in Medicare patients 65 years and older has increased 5% each year both because of our aging population and for other reasons that remain poorly defined.⁶ Consequently, there has been a 66% increase in hospital admissions for AF over the past 20 years. It is estimated that AF will affect up to 12 million people in the United States by the year 2050.⁷ Its financial burden is significant, with a global annual cost of \$8705 per patient annually, and \$6 billion in the United States alone.⁸ Although AF is frequently considered to be an innocuous arrhythmia, it can be associated with significant morbidity and mortality because of its three detrimental sequelae: (1) palpitations, which cause the patient discomfort and anxiety; (2) loss of synchronous atrioventricular contraction, which compromises cardiac hemodynamics,

resulting in varying degrees of ventricular dysfunction; and (3) stasis of blood flow in the left atrium, which can result in thromboembolism and stroke.⁹⁻¹³ Separate from the direct cardiac effects, the most feared complications of AF stem from the development of thrombus in the left atrium. These thrombi can embolize and lead to myocardial infarction, acute mesenteric ischemia, and stroke. Stroke, in particular, is three to five times more likely to occur in patients with AF when compared to patients in sinus rhythm.¹⁴ Conversely, 20% to 30% of all acute stroke patients are found to be in AF.¹⁵⁻¹⁷ Antiarrhythmic medications have largely been unsuccessful thus far, with most series showing the efficacy of antiarrhythmic medications to be less than 50%.¹⁸⁻²⁰ Antithrombotic drugs for AF carry with them various complications, including an annual risk of major bleeding up to 3%, rising even higher in older adults.^{17,21,22} AF also independently increases mortality rates. Using data from the Framingham Heart Study, Benjamin and coworkers established the risk factor-adjusted odds ratio for death in men and women with AF as 1.5 and 1.9, respectively.²³

Classification of Atrial Fibrillation

AF can be classified in various ways, but the classification system published jointly by the American Heart Association, the American College of Cardiology, and the Heart Rhythm Society is the most widely used.²⁴ This system defines AF as either paroxysmal or persistent. When a patient has had two or more episodes, AF is considered recurrent. If recurrent AF terminates spontaneously, it is designated paroxysmal, but if it is sustained beyond 7 days, it is termed persistent. Termination by pharmacologic therapy or electrical cardioversion before expected spontaneous termination does not change the designation *persistent*. In a recent consensus statement sponsored by the Heart Rhythm Society, the definition of *permanent* was changed to include only cases in which cardioversion has failed, clarifying that patients with long-standing AF might still be cured by intervention. In those cases, *permanent* has been replaced with the term *long-standing AF* when the duration is more than 1 year.²⁵

Electrophysiology of Atrial Fibrillation

AF is characterized by the irregular activation of the atria and an accompanying irregular ventricular response. Activation of the atria during AF can exhibit two different patterns. One pattern consists of a stable source, either a focal trigger or a small reentrant circuit, with fibrillatory conduction away from the source. The other pattern is characterized by multiple changing sources or reentrant circuits. The specific mechanism may change over time in a particular patient. Work from our laboratory obtained from patients undergoing intraoperative mapping before arrhythmia surgery revealed that the source of AF was not stable in almost half of the patients, even moving from one atrium to the other.²⁶

Four substrates determine whether AF is initiated and sustained: (1) a trigger, usually a premature depolarization or runs of focal ectopic depolarizations; (2) the refractory period of the atria and its magnitude and

spatial distribution; (3) the conduction velocity and its magnitude and anisotropic spread; and (4) the geometry or anatomy, both macroscopic and microscopic. Whatever the pathologic process (e.g., valvular disease, heart failure, ischemia, tachycardia, pericarditis, or inflammation) is, the changes that occur affect one or more of these four factors.²⁷

The surgical treatment of AF is directed at alteration of the geometry and anatomy needed to support AF. Non-reentrant mechanisms, such as abnormal automaticity and triggered activity, are important for the generation of premature beats, which act as a trigger for reentry but may also be involved in maintaining AF. The premature beats interact with the underlying distribution of refractory periods. As the distribution becomes more inhomogeneous, unidirectional block can occur. This is a necessary condition for the initiation of reentry. When unidirectional block occurs, a reentrant arrhythmia will occur only if a critical mass of tissue is present. The critical mass is determined by the tissue geometry, the magnitude of refractory periods, and the conduction velocity. The amount of tissue required to support a reentrant circuit is defined by the equation $WL = CV \times RP$ (wavelength = conduction velocity $\times$ refractory period). If either CV or RP decreases, the amount of tissue needed to sustain AF decreases, and the probability of a patient's having an arrhythmia increases.²⁸ Interventional approaches attempt to alter one of these substrates. However, any treatment strategy has the potential to affect the other substrates that cause AF. For example, incisions or ablations not only affect conduction, but they also alter the geometry of the atria, decrease viable myocardial mass, and can denervate regions of the atria, which alters refractory periods.²⁸

A great deal of emphasis has been placed on the role of the pulmonary veins in the triggering of AF. Paroxysmal AF often originates in the pulmonary veins.²⁹ In humans, the anatomy of the pulmonary veins is variable, with electrically excitable cardiac muscle extending 1 to 4 cm beyond the ostium of the veins.³⁰ Developmental biological studies suggest that pacemaker tissue may be present in the pulmonary veins.³¹ Another potential mechanism of focal activation is afterdepolarization.³² Intraoperative mapping studies have shown ectopic atrial beats originating from the region of the pulmonary veins.²⁷ Biatrial mapping studies by Schmitt and coworkers³³ have shown that the premature beats that trigger AF were located in the pulmonary veins 53% of the time and in the posterior atrium in another 29% of cases.

Successful cure of AF is achieved in some patients by the isolation of the pulmonary veins.²⁹ Furthermore, if triggers of AF were outside the pulmonary veins but other substrates that sustain AF were within the veins, AF would be prevented with pulmonary vein isolation. The failure to cure AF by isolating only the pulmonary veins in some patients, especially those with long-standing AF, suggests that other anatomic triggers or more complicated mechanisms may be involved in these cases. Using intraoperative mapping in patients with mitral valve disease, Nitta and colleagues³⁴ determined that atrial focal activation is one mechanism of AF. Caution should be taken in interpreting various interventional

studies, whether catheter ablation or surgery, as to whether they imply an underlying mechanism involved in a patient's AF. Most intraoperative and catheter mapping systems do not have the spatial resolution within the pulmonary veins to separate reentrant from non-reentrant mechanisms. Therefore, even though "focal" fibrillation may be reported from investigational mapping, this does not rule out reentry as a mechanism underlying the arrhythmia. Claims of cure by pulmonary vein isolation alone must be tempered by the knowledge that the "pulmonary vein isolation" intervention actually incorporates much more than just the pulmonary veins. Commonly, the pulmonary veins, the adjacent atrial muscle, and the muscle in the oblique sinus between the veins are ablated during catheter-based pulmonary vein isolation. This area is more than one third of the left atrium. This large area of ablation substantially reduces the critical mass needed to sustain AF and may incorporate other non-pulmonary vein substrates of AF.

The definitions of paroxysmal, persistent, and long-standing AF do not imply a specific mechanism. Even though clinical results have shown that pulmonary vein isolation is effective 70% to 80% of the time in paroxysmal AF, it is clear that the pulmonary veins are not the only substrate driving AF 20% to 30% of the time.²⁶ Similarly, in persistent AF, pulmonary vein isolation alone is successful in only a small number of patients.²⁵ Human mapping data from our laboratory did not show any significant difference in mechanism between paroxysmal and persistent AF.²⁶ Current diagnostic technologies rarely allow a preoperative delineation of mechanism. However, electrophysiologic studies may allow physicians to identify triggers of AF in some patients.²⁶ Because AF is a complex arrhythmia, mapping requires a high density of closely placed electrodes as well as a sophisticated mapping and signal processing system to define the particular mechanism in an individual patient. In our experience, intraoperative mapping has not been useful in providing real-time information during surgery. The analysis of this complex arrhythmia is time-consuming and difficult. Therefore, the traditional surgical algorithm of obtaining preoperative or intraoperative mapping data and using this information to guide the specific surgical technique, as was done with arrhythmias such as Wolff-Parkinson-White syndrome, has not been feasible for AF. Mapping techniques are currently being developed that may allow interventionalists to customize the lesion set to the specific underlying mechanism.^{26,34-36}

One particularly promising technique is electrocardiographic imaging.³⁷ This technology allows AF to be mapped noninvasively in the awake patient by recording signals from the body surface and solving the inverse equation. This would delineate the mechanism before the proposed intervention and may allow physicians to triage patients to the most effective procedure.

Medical Treatment

Results with medical therapy alone for AF have been disappointing. Antiarrhythmic drugs have had limited long-term efficacy in converting AF to normal sinus rhythm and have significant and sometimes fatal side

effects.³⁸⁻⁴³ The goal of pharmacotherapy is therefore often shifted from *rhythm* to *rate* control, which involves slowing the ventricular response rate to AF, thus avoiding the development of rate-related cardiomyopathy and symptoms such as palpitations. The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) study^{44,45} showed that management with rhythm control did not have any survival benefit over a rate control strategy in anticoagulated patients with AF.^{46,47} Furthermore, rate control strategy may potentially have advantages over rhythm control, such as a lower risk for adverse side effects.⁴⁶

Rate control alone clearly has disadvantages. Although the ventricular response rate can often be controlled pharmacologically, the atria are still in fibrillation. With persistent AF, two of the three detrimental sequelae associated with AF persist. In patients with baseline cardiac dysfunction, the absence of atrial "kick" often can result in worsening symptoms of congestive heart failure. Most important, patients with AF are at risk for developing thromboembolism, requiring indefinite anticoagulation with warfarin or one of the newer anticoagulants, such as dabigatran, rivaroxaban, or apixaban.⁴⁸ The use of warfarin is associated with a major complication rate of approximately 2% per year.⁴⁹⁻⁵¹ Although these newer anticoagulants decrease the risk of intracerebral hemorrhage without the need for routine coagulation monitoring, they have the same effectiveness as warfarin in the reduction of thromboembolism.⁴⁸

Despite the results from the AFFIRM trial supporting no difference in long-term outcome between rhythm and rate control, there are many clinically meaningful advantages of being in normal sinus rhythm. These advantages include increased exercise tolerance, no need for anticoagulation, decreased palpitations, and prevention of atrial remodeling.^{45,52} Most important, when time-dependent variables were evaluated in the AFFIRM trial, the presence of sinus rhythm was associated with a significantly decreased risk of death (hazard ratio = 0.53; $P < 0.0001$).⁵³ Thus, the AFFIRM trial demonstrated that antiarrhythmic drugs are detrimental and that normal sinus rhythm is beneficial in this population of patients, suggesting a role for nonpharmacologic restoration of sinus rhythm.

Historical Aspects of Surgery for Atrial Fibrillation

Because of the inadequacy of medical therapy for AF, several procedures were developed in the 1980s aimed at treatment of AF. Most of these were abandoned because of their inability to eliminate all three of the detrimental sequelae associated with AF.⁵⁴⁻⁵⁶ Nevertheless, they helped physicians gain fundamental knowledge about the mechanism of AF and laid a foundation for the development of the Cox-Maze procedure and its subsequent iterations. The Cox-Maze procedure is recognized today as the gold standard for surgical cure of AF. The next section briefly describes these various surgical procedures developed in an attempt to cure AF.

Left Atrial Isolation Procedure. In 1980, Dr. James L. Cox and his group developed the left atrial isolation

procedure, which confined AF to the left atrium, thus restoring the remainder of the heart to normal sinus rhythm.⁵⁶ This procedure had the advantage of restoring normal atrioventricular rhythm without requiring a permanent pacemaker. Because the sinoatrial node, atrioventricular node, and internodal conduction pathways are located in the right atrium and interatrial septum, the left atrial isolation procedure did not interfere with normal atrioventricular conduction.

Electrical isolation of the left atrium also unexpectedly restored normal cardiac hemodynamics. This occurred because the right atrium and the right ventricle contracted in synchrony after the procedure, providing a normal right-sided cardiac output that was then delivered to the left side of the heart. Although the left atrium was isolated, the left ventricle adapted immediately to the normal right-sided cardiac output and delivered a normal forward cardiac output.

By confining AF to the left atrium only, the left atrial isolation procedure eliminated two of the three detrimental sequelae of AF: irregular heartbeat and compromised cardiac hemodynamics. However, because the electrically isolated left atrium remained in AF, this procedure did not eliminate the risk of thromboembolism. It also did not address patients in whom the AF originated in the right atrium.

Catheter Ablation of the Atrioventricular Node–His Bundle Complex. In 1982, Scheinman and colleagues⁵⁷ described the catheter fulguration of the His bundle, which controlled the irregular cardiac rhythm associated with AF and other refractory supraventricular arrhythmias. Similar to the left atrial isolation procedure, this procedure electrically isolated the arrhythmia to the atria. However, ablation of the His bundle necessitated implanting a permanent ventricular pacemaker to restore normal ventricular rhythm.

Unfortunately, His bundle ablation eliminated only the irregular heart beat. Both atria still remained in fibrillation, and the vulnerability to thromboembolism was unaffected. Atrioventricular contraction remained desynchronized, compromising cardiac hemodynamics. Despite its drawbacks, this remains a common treatment for medically refractory AF in patients not considered good candidates for a more curative interventional procedure.

Corridor Procedure. In 1985, Guiraudon and associates⁵⁸ introduced the corridor procedure for the treatment of AF. This was an operation that isolated a strip of atrial septum harboring both the sinoatrial node and the atrioventricular node, thereby allowing the sinoatrial node to drive the ventricles. This procedure corrected the irregular heart beat associated with AF, but both atria either remained in fibrillation or developed their own asynchronous intrinsic rhythm because they were isolated from the septal “corridor.” The atria were also isolated from their respective ventricles, thereby precluding the possibility of atrioventricular synchrony. The corridor procedure was abandoned because neither the hemodynamic compromise nor the risk of thromboembolism associated with AF was addressed.

Atrial Transection Procedure. All three surgical procedures developed in the early 1980s had attempted to isolate and to confine AF to a certain region of the atria, stopping it from propagating its effects to the ventricles. None of these procedures was targeted to cure AF.

In 1985, Cox’s group described for the first time a series of experiments that attempted to cure AF in a canine model.⁵⁹ After a number of experiments, it was found that a single long incision across both atria and down into the septum cured AF. This “atrial transection” procedure prevented the induction and maintenance of AF or atrial flutter in canines.⁶⁰ Unfortunately, this procedure was not successful in its clinical application.

Development of the Cox-Maze Procedure

The first successful curative surgical procedure for the treatment of AF was introduced clinically in 1987 by the team led by Dr. James L. Cox at Washington University in St. Louis.⁶⁰⁻⁶² The Cox-Maze procedure was designed to interrupt the macro-reentrant circuits that were thought to be responsible for AF, thereby precluding the ability of the atrium to flutter or fibrillate (Fig. 87-1). In contrast to previous procedures, the Maze procedure successfully restored both atrioventricular synchrony and a regular heart beat, thus decreasing the risk of thromboembolism and stroke.⁶³ The operation involved creating myriad incisions across both the right and left atria. The surgical incisions were placed so that the sinoatrial node could “drive” the propagation of the sinus impulse throughout both atria. It also allowed all of the atrial myocardium to be activated, resulting in preservation of atrial transport function in most patients.⁶⁴

After almost a decade of basic research, the Maze I procedure was introduced in 1987, only to be soon modified to become the Maze II procedure because of late chronotropic incompetence and a high incidence of pacemaker implantations. The Maze II procedure, however, proved to be too technically difficult to perform. It was therefore further modified and renamed the Maze III procedure (Fig. 87-2).^{65,66}

During the 1990s, the Cox-Maze III procedure became the gold standard for the surgical treatment of AF. In a long-term study of patients who had the Cox-Maze procedure, 97% of the patients at late follow-up were free of AF.⁶⁷ Similar results have been reproduced by other institutions around the world.⁶⁸⁻⁷⁰

Surgical Ablation Technology

Despite its proven efficacy, the Cox-Maze III procedure did not gain widespread acceptance. Few cardiac surgeons were willing to add the procedure to coronary revascularization or valve procedures because of its complexity and technical difficulty. In an attempt to simplify the operation, groups around the world have replaced the incisions of the traditional cut-and-sew Cox-Maze III procedure with linear lines of ablation.⁷¹ These linear lines of ablation have been created by use of a variety of energy sources, including radiofrequency energy, microwave, cryoablation, laser, and high-frequency ultrasound.

FIGURE 87-1 ■ Original conceptual design of the Cox-Maze procedure for atrial fibrillation. Both atrial appendages were excised, and the pulmonary veins were isolated. AVN, Atrioventricular node; LAA, left atrial appendage; PVs, pulmonary veins; RAA, right atrial appendage; SAN, sinoatrial node. (From Cox JL, Canavan TE, Schuessler RB, et al: The surgical treatment of atrial fibrillation. II. Intraoperative electrophysiologic mapping and description of the electrophysiologic basis of atrial flutter and atrial fibrillation. *J Thorac Cardiovasc Surg* 101:406–426, 1991.)

FIGURE 87-2 ■ Two-dimensional drawing depicting the atrial incisions of the Cox-Maze III procedure. (From Cox JL, Boineau JP, Schuessler RB, et al: Modification of the maze procedure for atrial flutter and atrial fibrillation. I. Rationale and surgical results. *J Thorac Cardiovasc Surg* 110:473–484, 1995.)

The development of these new ablation technologies revolutionized the surgical treatment of AF by taking a technically difficult and time-consuming operation and making it relatively easy for most cardiac surgeons to perform. Whereas very few patients (<1%) with AF undergoing cardiac surgery before 2000 underwent a Cox-Maze procedure, a study has shown that more than 40% of patients with AF undergoing cardiac surgery had a concomitant ablation procedure in 2006.^{72,73} Another advantage of ablation technologies is that they have facilitated the development of less invasive operations. A minimally invasive beating heart procedure with high efficacy is the ultimate goal of these efforts. With the availability of easy-to-use ablation devices, numerous groups around the world have introduced new procedures for AF

involving more limited sets of atrial lesions. Some groups are currently performing only the left atrial lesions, whereas others are advocating pulmonary vein isolation alone. Results with these more limited procedures are discussed in a later section.

For ablation technology to reliably replace the incisions in AF surgery, it must meet several criteria. Foremost, it must reliably produce bidirectional conduction block. This is the mechanism by which incisions prevent AF: by blocking macro-reentrant or micro-reentrant circuits, by isolating trigger foci, or by reducing atrial contiguous mass. To do this with certainty, an ablation device must have the capability to reliably make transmural lesions from either the epicardial or the endocardial surface. Experimental work from our laboratory has shown that even gaps as small as 1 mm in ablation lines can conduct fibrillatory wavefronts.⁷⁴

The second crucial characteristic of an ablation device is safety. This requires a precise definition of dose-response curves to limit excessive or inadequate ablation. The surgeon must have knowledge of the effect of the specific ablation technology on surrounding vital cardiac structures, such as the coronary sinus, coronary arteries, and valves. Third, a device should make AF surgery simpler and require less time for it to be performed. This requires features such as rapidity of lesion formation, simplicity of use, and adequacy of length and flexibility. Finally, the device ideally should be adaptable to a minimally invasive approach. This would require the ability to insert the device through small incisions or ports. It would also be beneficial for the device to be capable of creating epicardial transmural lesions on the beating heart.

The current ablation technologies with their advantages and disadvantages are briefly described in this section. At present, there are no microwave, ultrasound, or laser ablation devices on the market and these energy

sources are not discussed. There is still no perfect ablation device. As new devices are introduced in the future, it will be imperative to rigorously examine the effects of the new technology on atrial hemodynamics and electrophysiology.

Radiofrequency Energy

Radiofrequency (RF) energy has been used for cardiac ablation for many years in the electrophysiology laboratory.⁷⁵ It also was one of the first energy sources to be used in the operating room. RF energy can be delivered by either unipolar or bipolar electrodes, and the electrodes can be either dry or irrigated.

There have been numerous unipolar RF devices available for ablation. Estech (San Ramon, CA) has marketed several devices, both dry and irrigated unipolar catheters that are segmented and flexible. These devices can create variable lesion lengths of 10 to 95 mm. The electrodes can be individually selected and temperature controlled. Later iterations have included suction stabilization. The devices are targeted for use in the minimally invasive setting, but they have yet to approach the same degree of transmural ablation that has been achieved with bipolar RF clamps. Both Medtronic and Estech have developed irrigated unipolar RF devices that are used to make point-by-point ablations by dragging the device across tissue to make a linear lesion.

Bipolar RF is similar to unipolar energy except that two electrodes, instead of one, are used to focus the path of energy. This allows faster ablation (usually less than 20 seconds) while focusing destruction to tissue that is within the clamp. With bipolar devices, the electrodes are clamped over the targeted atrial tissue. The first bipolar RF device was introduced by AtriCure, Inc. The Isolator was a specially designed clamp with 1-mm-wide, 5-cm-long electrodes embedded in the jaws of the clamp. The device was unique in that it had an algorithm created to provide a real-time measurement of lesion transmural ablation. The conductance between the electrodes was measured during ablation. When the conductance dropped to a stable minimum level, this correlated well both experimentally and clinically to histologically transmural lesions.⁷⁶⁻⁷⁸ More recent iterations have introduced more uniform clamp strength and a dual electrode design to achieve wider and more consistent lesions.

Other RF ablation devices have been released.^{79,80} The Cobra Adhere and Cobra Adhere XL (Estech, San Ramon, CA) devices are streamlined with suction stabilization for use in minimally invasive procedures, such as port access and thoroscopic approaches. The Cobra Fusion (Estech, San Ramon, CA) includes suction stabilization and has a unique electrode configuration to allow both unipolar and bipolar RF ablation.⁸¹ The Medtronic bipolar devices, the Cardioblate BP2 and Cardioblate LP, have an irrigated, flexible jaw along with an articulating head, with 7-cm-long electrodes. These devices have an algorithm to predict transmural ablation of lesions that has been shown to be effective in experimental and clinical settings.^{82,83}

RF energy uses an alternating current in the range of 100 to 1000 kHz. This frequency is high enough to prevent rapid myocardial depolarization and the

induction of ventricular fibrillation, yet low enough to avoid tissue vaporization and perforation. Resistive heating occurs only within a narrow rim of tissue in direct contact with the electrode, usually less than 1 mm. The deeper tissue heating occurs by passive conduction. With unipolar catheters, the energy is dispersed between the electrode tip and an indifferent electrode, usually the grounding pad applied to the patient. In the bipolar clamp devices, alternating current is generated between two closely approximated electrodes, which results in a more focused ablation. The lesion size depends on the electrode-tissue contact area, the interface temperature, the current and voltage (power), and the duration of delivery. The depth of the lesion can be limited by char formation at the tissue-electrode interface because of the high temperatures (>100°C). To resolve this problem, irrigated catheters have been developed; this reduces char formation by keeping temperatures cooler at the tissue interface. These irrigated catheters have been shown to create larger volume lesions than those created by the dry RF devices.^{84,85}

Dose-response curves for unipolar RF have been described.⁸⁶⁻⁸⁸ Although unipolar RF has been shown to create transmural lesions on the arrested heart in animals with sufficiently long ablation times (60 to 120 seconds), this has not been the case in humans. In one study, after 2-minute endocardial ablations during mitral valve surgery, only 20% of the *in vivo* lesions were transmural.⁸⁷ Epicardial ablation has been even more difficult. Animal studies have consistently shown that unipolar RF is incapable of creating epicardial transmural lesions on the beating heart.^{88,89} Another study in humans resulted in only 7% of lesions being transmural despite electrode temperatures of up to 90°C.⁹⁰ The Cobra Adhere is an epicardial suction-stabilized unipolar RF ablation device. Despite the proposed advantages of epicardial ablation, the Cobra Adhere demonstrated only 40% full-thickness ablation of sectioned ablations after a 2-minute ablation period in animal testing. In particular, the device showed difficulty creating full-thickness lesions in atrial tissue thicker than 3 mm.⁹¹ Bipolar RF ablation, on the other hand, has been shown to be capable of creating reliable transmural lesions on the beating heart in animals with average ablation times between 5 and 10 seconds.^{76,77,92} Newer devices such as the Cobra Fusion have included a combination of both unipolar and bipolar ablation along with the use of proprietary impedance algorithms to determine the amount of time necessary for ablation. Similar animal studies have shown the Cobra Fusion to create transmural lesions in 94% of sectioned lesions.⁸¹

Because RF ablation is a well-developed technology, much is known about its safety profile. Clinical complications of unipolar RF devices have been described, including coronary artery injuries, cerebrovascular accidents, and the devastating complication of esophageal perforation leading to atri-esophageal fistula.⁹³⁻⁹⁶ Use of the bipolar RF devices has eliminated virtually all the collateral damage seen with the unipolar devices, and there have been no clinical complications reported in the literature. Unfortunately, at this time bipolar devices have the drawback of requiring that the tissue be clamped in the jaws of the device to consistently make transmural lesions. This has limited the potential lesion set,

particularly on the beating heart through a minimally invasive epicardial approach, and has required the use of adjunctive unipolar technology to create a complete Cox-Maze lesion set.

Cryoablation

Currently two commercially available sources of cryothermal energy are available. One technology uses nitrous oxide and is manufactured by AtriCure (Cincinnati, OH). The nitrous oxide devices use both rigid reusable and flexible disposable electrodes. More recently, devices using argon were introduced. The technology is now distributed by Medtronic (Minneapolis, MN). This device originally consisted of a disposable flexible catheter that had a 6-cm ablation probe. Newer iterations have included a 10-cm ablation electrode with the addition of a removable clamp. At 1 atmosphere of pressure, nitrous oxide is capable of cooling tissue to -89.5°C ; argon has a minimum temperature of -185.7°C .

The size and depth of cryolesions are determined by numerous factors, including probe temperature, tissue temperature, probe size, duration and number of ablations, and the liquid used as the cooling agent.⁹⁷ With conventional nitrous oxide, 2- to 3-minute ablations have been shown to reliably create transmural lesions on both the right and the left atrium. Because of the heat sink provided by circulating endocardial blood, epicardial cryolesions on the beating heart have not been uniformly transmural.⁹⁸ In one study, investigators were able to create transmural lesions 62% of the time around the pulmonary veins, and two of eight ablations (25%) on the left atrial appendage were transmural.⁹⁸ However, in another study of cryoablation on the beating heart, consistent transmural lesions were created on tissue up to 7 mm thick.⁹⁹ Ablations were performed around the pulmonary veins, and acute electrical isolation was achieved in 13 of 13 animals. Although histologic analysis revealed 89% of sections achieved transmural lesions, none of the box lesions around the pulmonary veins was completely transmural, again emphasizing the drawbacks of cryoablation on the beating heart.

Because of its ease of use and safety profile, cryoablation remains popular for the treatment of AF. A European randomized trial comparing mitral valve surgery alone with mitral valve surgery with left atrial ablations found an increase in cure for AF in the cryoablation group (freedom from AF at 12 months: 43% vs. 73%).¹⁰⁰

Cryoablation has the benefit of preserving the fibrous skeleton of the heart, making this an ideal choice for ablation near valvular tissue. Nitrous oxide cryoablation has had extensive clinical use and has had an excellent safety profile. Although cryothermal energy appears to have no permanent effects on valvular tissue or the coronary sinus, experimental studies have shown late intimal hyperplasia of coronary arteries, and these structures should be avoided.¹⁰¹⁻¹⁰⁴ Doll and colleagues⁹⁸ were able to create mild esophageal lesions with epicardial cryoablation in seven of eight cases.

Cryoablation is unique among the currently available ablation technologies in that it destroys tissue by freezing rather than by heating. The important advantage is its

ability to preserve tissue architecture. The potential disadvantages of cryoablation technology include the relatively long time necessary to create a lesion (1 to 3 minutes) and the difficulty in creating lesions on the beating heart. Furthermore, if blood is frozen during epicardial ablation on the beating heart, it coagulates, creating a potential risk of thromboembolism.

Surgical Indications for Treatment of Atrial Fibrillation

The principal indication for surgery for AF is intolerance of the arrhythmia in patients for whom medical management has failed. Patients with paroxysmal atrial flutter or fibrillation are often more symptomatic than those with persistent or long-standing AF. Major symptoms include dyspnea on exertion, easy fatigability, lethargy, palpitations, and general sense of unease. Before surgery, all patients should have a trial of medical management.

The Heart Rhythm Society created a task force to evaluate indications for catheter and for surgical ablation of AF.^{25,105} The recommendations were developed in partnership with the European Heart Rhythm Association, the European Cardiac Arrhythmia Society, the American College of Cardiology, the American Heart Association, and the Society of Thoracic Surgeons. The task force recommended that programs involved in the stand-alone surgical treatment of AF should develop a team approach to these patients, including electrophysiologists and surgeons, to ensure appropriate patient selection. The consensus of the task force was that the following were appropriate indications for surgical ablation of AF: (1) symptomatic AF patients undergoing other cardiac surgical procedures and (2) selected asymptomatic AF patients undergoing cardiac surgery in whom the ablation can be performed with minimal risk. Stand-alone AF surgery should be considered for symptomatic AF patients who have failed medical management and either prefer a surgical approach, have failed one or more attempts at catheter ablation, or are not candidates for catheter ablation.^{25,105}

Other patients who should be considered for surgery include those who have developed a contraindication to warfarin or who have had a stroke while adequately anticoagulated. The Cox-Maze procedure significantly reduces the risk of stroke in these patients. Approximately 20% of patients who had the original cut-and-sew procedure at our institution had experienced at least one episode of cerebral thromboembolism that resulted in a temporary or permanent neurologic deficit before having the Cox-Maze procedure; less than 2% of patients (6 of 389) had a late neurologic event after surgery (mean follow-up of 6.6 years).¹⁰⁶

Surgical Technique: Cox-Maze Procedure

The final version of the standard cut-and-sew technique to cure AF was the Cox-Maze III procedure.^{60,107-109}

However, few cardiac surgeons performed this operation because of its technical complexity. Most centers have replaced most surgical incisions with linear lines of ablation created by various energy sources. At Washington

FIGURE 87-3 ■ Cox-Maze IV procedure lesion set. Modifications included independent isolation of pulmonary veins with connecting lesions and no atrial septal incision (originally used for exposure). IVC, Inferior vena cava; SVC, superior vena cava.

University, bipolar RF energy and cryoenergy have been used successfully to replace most surgical incisions of the Cox-Maze III procedure. Our current procedure incorporates most of the lesions of the Cox-Maze III procedure and has been named the Cox-Maze IV (Fig. 87-3).¹¹⁰ Our clinical data have shown that this modified operation has significantly shortened the operative time while maintaining the high success rate of the traditional cut-and-sew Cox-Maze III procedure.¹¹¹

Bipolar RF ablation was chosen for the Cox-Maze IV procedure for several reasons. First, the device allows the on-line determination of lesion transmural by measuring the conductance between the two electrodes.^{76,77,87} Second, the bipolar RF device has short ablation times, with 5- to 6-cm-long transmural ablations performed in 5 to 15 seconds. Third, the lesions are narrow (2 to 3 mm in width), and tissue injury is confined to within the clamp. This eliminates the possibility of unwanted collateral injury.^{94,112-114}

The Cox-Maze IV procedure has three parts: (1) bilateral pulmonary vein isolation, (2) the right atrial lesion set, and (3) the left atrial lesion set with left atrial excision. The operation is often combined with other procedures and is performed through a sternotomy or a minimally invasive (4- to 5-cm) right mini-thoracotomy. The operation is performed using either central or femoral cannulation for cardiopulmonary bypass depending on the operative approach being a sternotomy or mini-thoracotomy, respectively. The standard sternotomy approach is described in the following paragraphs. The mini-thoracotomy approach was previously described by our group.¹¹⁵ All patients receive an intraoperative transesophageal echocardiogram to rule out the presence of left atrial clot and are electrically cardioverted followed by amiodarone infusion if found to be in AF at the time of surgery. It should be noted that each RF ablation line is created by performing two or three ablations with the clamp to ensure transmural.

Pulmonary Vein Isolation

With the patient in a supine position through a median sternotomy, a pericardial cradle is created, and the patient

FIGURE 87-4 ■ Right pulmonary vein isolation during Cox-Maze IV procedure. The bipolar radiofrequency device is placed around the right pulmonary veins. The device is clamped on the cuff of atrial tissue surrounding the pulmonary veins.

is centrally cannulated. Normothermic cardiopulmonary bypass is initiated. Both the right (Fig. 87-4) and the left (Fig. 87-5) pulmonary veins are bluntly dissected at their confluences and surrounded with umbilical tapes. If the patient is in AF, he or she is cardioverted at this point. The bipolar RF clamp is passed around the pulmonary veins on each side. Typically three ablations are performed to isolate as large an atrial cuff around the pulmonary veins as possible. Exit block is confirmed by attempting to pace from each pulmonary vein.

Right Atrial Lesion Set

The patient is cooled to 34° C. On the beating heart, a pursestring suture wide enough to accommodate one jaw of the bipolar RF clamp is made at the base of the right atrial appendage. Through this pursestring, an ablation line is created along the free wall of the right atrium down toward the junction of the right atrium and

FIGURE 87-5 ■ Left pulmonary vein isolation during Cox-Maze IV procedure. The bipolar radiofrequency device is placed around the left pulmonary veins. The device is clamped on the cuff of atrial tissue surrounding the pulmonary veins. (Modified with permission from AtriCure.)

FIGURE 87-6 ■ The right atrial free wall ablation. The bipolar radiofrequency clamp is placed through a pursestring suture in the base of the right atrial appendage and is carried down perpendicularly toward the superior vena cava. (Modified with permission from AtriCure.)

FIGURE 87-8 ■ Bipolar radiofrequency ablation along the superior vena cava and inferior vena cava through the right atriotomy, completing the right atrial lesion set. (Modified with permission from AtriCure.)

superior vena cava (Fig. 87-6). A vertical atriotomy is performed from the intra-atrial septum toward the atrio-ventricular groove, along the free wall of the right atrium at least 2 cm away from the previous RF ablation (Fig. 87-7). Cryoablation is then used for reasons mentioned previously in this chapter because of its ability to ablate without damaging valvular tissue. From the superior aspect of this atriotomy, a 3-cm linear cryoprobe is used to create an endocardial ablation down to the 2-o'clock position of the tricuspid valve. The cryoprobe is then placed through the pursestring suture at the base of the right atrial appendage, and a second linear endocardial ablation is created down toward the 10-o'clock position of the tricuspid valve. A final bipolar RF ablation line is created along the superior vena cava and down the inferior vena cava (Fig. 87-8).

Left Atrial Lesion Set

The aorta is cross-clamped and cold blood cardioplegia is administered. While the patient is under cardioplegic arrest, the left atrial appendage is amputated. Through this incision, one jaw of the RF ablation clamp is inserted and an ablation line is created to the superior left pulmonary vein. The left atrial appendage is oversewn in two layers. A standard left atriotomy is performed, which can be extended superiorly onto the dome of the left atrium and inferiorly around the orifice of the right inferior pulmonary vein. Two separate bipolar RF ablation lines are then created from both the superior and the inferior aspects of the atriotomy incision to the origin of the left superior and inferior pulmonary veins, respectively, thus completing the “box lesion” (Fig. 87-9). A final bipolar RF ablation line is created from the inferior aspect of the

FIGURE 87-9 ■ Completion of left atrial “box lesion” after creating a bipolar radiofrequency ablation line through the amputated atrial appendage to the left superior pulmonary vein and left atriotomy. (Modified with permission from AtriCure.)

FIGURE 87-10 ■ Bipolar radiofrequency ablation across the floor of the left atrium from the inferior aspect of the atriotomy to the mitral annulus. (Modified with permission from AtriCure.)

atriotomy, across the floor of the left atrium, down to the mitral valve annulus (Fig. 87-10). This ablation line should cross the coronary sinus ideally in the space between the circumflex and right coronary circulations. If the patient has a left dominant circulation, this lesion can be created surgically to identify and spare the circumflex artery, although this is rarely needed. The end of this RF ablation line is marked with methylene blue. This ablation line is connected to the mitral valve annulus by performing an endocardial cryoablation, which overlaps onto the posterior leaflet of the mitral valve. A second epicardial cryoablation is performed simultaneously over the coronary sinus with a linear cryoprobe to complete the left atrial isthmus ablation. This should directly oppose the endocardial cryoablation (Fig. 87-11).

Surgical Results: Cox-Maze Procedure

The long-term results of the Cox-Maze III procedure have been excellent. In our series of 198 consecutive

FIGURE 87-11 ■ Epicardial cryoablation over the coronary sinus completing the left atrial isthmus line. Note that this figure does not show simultaneous endocardial ablation over the mitral annulus, which is typically performed. (Modified with permission from AtriCure.)

FIGURE 87-12 ■ Kaplan-Meier analysis of freedom from recurrent atrial fibrillation. The numbers on each line indicate the number of patients at risk. There was no difference in the long-term estimate of freedom from atrial fibrillation between the lone Cox-Maze procedure (L) group and the concomitant (C) group ($P = 0.64$). AF, Atrial fibrillation. (From Prasad SM, Maniar HS, Camillo CJ, et al: The Cox Maze III procedure for atrial fibrillation: long-term efficacy in patients undergoing lone versus concomitant procedures. *J Thorac Cardiovasc Surg* 126:1822–1828, 2003.)

patients undergoing surgery, 97% of patients at a mean follow-up of 5.4 years were free from symptomatic AF (Fig. 87-12). There was no difference in cure rates between patients undergoing a lone versus a concomitant procedure. The cure rates off antiarrhythmic medications were 80% and 73%, respectively, in patients undergoing lone and concomitant Cox-Maze procedures at late follow-up.¹¹⁶

Our results using bipolar RF ablation (Cox-Maze IV) have been similarly encouraging. In a prospective, single-center trial from our institution, 91% of patients at 6 months of follow-up were free from AF. The operative mortality was 0%.⁹² More recently, we prospectively evaluated 100 consecutive patients and demonstrated postoperative freedom from AF at 93%, 90%, and 90% at 6, 12, and 24 months, respectively.¹¹⁷ A multicenter

FIGURE 87-13 ■ Pulmonary vein isolation methods. **A**, Left and right pulmonary veins are isolated separately. **B**, Left and right pulmonary veins are isolated separately and then connected with an additional lesion. **C**, Left and right pulmonary veins are isolated separately and connected inferiorly and superiorly, also referred to as a *box lesion*.

trial of the same technology had similar results.¹¹⁸ At 6 months, 96% of patients were in normal sinus rhythm, and there was no operative mortality in this group of 30 patients.⁶³ The modifications with use of bipolar RF have shortened the operation considerably while decreasing the major complication rate. The mean cross-clamp time for patients undergoing a lone Cox-Maze III procedure was 92 ± 26 minutes compared with 41 ± 13 minutes with the Cox-Maze IV.¹¹⁹ The same study demonstrated a major complication rate of 10% in the Cox-Maze III, which was significantly higher than the Cox-Maze IV cohort ($P = 0.004$). Two-year freedom from AF off antiarrhythmics using Holter monitoring was 84%, which was similar to previous reports of the Cox-Maze III documenting an 80% freedom from AF off antiarrhythmics using symptomatic reporting.¹¹⁹

The Cox-Maze IV procedure involves a lesion set around all the pulmonary veins, isolating the entire posterior left atrium by creating a “box” or by a simple connecting lesion between the pulmonary veins with a single ablation (Fig. 87-13). Our group demonstrated that isolation of the entire posterior left atrium by the creation of a box lesion had a significantly lower incidence of early atrial tachyarrhythmias, a higher freedom from AF recurrence at 1 and 3 months, and lower use of antiarrhythmic drugs at 3 and 6 months.¹²⁰ Furthermore, patients receiving a complete box lesion set had significantly higher freedom from AF and freedom from AF off antiarrhythmic drugs at 1 year compared with patients receiving a non-box ablation set (Fig. 87-14).¹¹⁷

The Cox-Maze procedure has also been effective at decreasing the risk of late stroke in this high-risk population of patients. In a report from our institution, 57 of 389 patients (14%) had experienced a neurologic event before surgery. Despite the inherently high risk of stroke in these patients, there were only six neurologic events during long-term follow-up (mean, 6.6 ± 5.0). The long-term stroke rate after the Cox-Maze procedure has been 0.2% per year despite the fact that the majority of patients were able to discontinue anticoagulation.¹⁰⁶

In a series from Japan, the Cox-Maze procedure was found to significantly decrease the incidence of late stroke, even in those patients already receiving anticoagulation for mechanical mitral valves. Patients with chronic AF who had a concomitant Cox-Maze procedure with their mitral valve replacement were 99% stroke free at a follow-up of 8 years, whereas the group with

FIGURE 87-14 ■ Freedom from atrial fibrillation on and off antiarrhythmic (ATA) drugs; comparison of box and non-box lesion sets at 12 months. (From Weimar T, Bailey MS, Watanabe Y, et al: The Cox-Maze IV procedure for lone atrial fibrillation: a single center experience in 100 consecutive patients. *J Interv Card Electrophysiol* 31:47–54, 2011.)

mitral valve replacement alone had only an 89% freedom from stroke.¹²¹

Surgical Technique: Other Atrial Fibrillation Procedures

A number of more limited surgical procedures have been proposed for the cure of AF. These procedures generally fall into two groups. The first group comprises those that incorporate only left atrial lesions, and the second group consists of procedures involving pulmonary vein isolation alone with or without ganglion ablation. The left atrial lesion set generally involves pulmonary vein isolation (either as a box or separately with a connecting lesion) and a lesion to the mitral annulus as well as removal of the left atrial appendage. These lesions have been created with many different energy sources, including unipolar and bipolar RF, cryoablation, and microwave.^{93,122–130} The specific technique often depends on the type of device used and has most often been performed on cardiopulmonary bypass.

A number of surgeons have published reports on the technique of pulmonary vein isolation alone for AF.¹³¹⁻¹³⁴ This limited lesion set can be done separately, with a connecting lesion, or as a box lesion (see Fig. 87-13). Various devices have been used to create these lesions, including RF, cryoablation, microwave energy, high-frequency ultrasound, and laser. Pulmonary vein isolation alone is attractive because it can be done without the use of cardiopulmonary bypass and often in a minimally invasive setting. Some investigators have proposed isolation of the pulmonary veins and also ablation of the ganglionic plexi.¹³⁵⁻¹³⁷

Pruitt and colleagues¹³⁸ reported on a minimally invasive technique used on 100 patients. The procedure was accomplished thoracoscopically without cardiopulmonary bypass through use of a unipolar microwave catheter. Wolf and coworkers¹³¹ published a report on a similar technique of bilateral video-assisted thoracoscopic off-pump epicardial pulmonary vein isolation using a bipolar RF clamp. This procedure was performed with two 10-mm ports and one 5- or 6-cm working incision on each side of the thorax. The right-sided pulmonary veins were first isolated while the patient was left side down, and then the patient was repositioned with the opposite side up for the left-sided lesions, including the division of the ligament of Marshall. Finally, the left atrial appendage was resected with an endoscopic stapling device.

A modified version of this approach has been practiced by our group. After double-lumen endotracheal tube intubation, appropriate central venous access, and monitoring (including transesophageal echocardiography to evaluate for left atrial thrombus), the patient is placed left side down with the right arm positioned to expose the right axilla. The third or fourth intercostal space, midaxillary line, scapula, and xiphoid are marked, and the right side of the chest is prepared and draped from the spine to the sternum. A 10- or 12-mm port is placed in the sixth intercostal space approximately 2 cm anterior to the midaxillary line, typically at the level of the xiphoid (Fig. 87-15). Carbon dioxide is insufflated to flood the air space. A 30-degree scope is used to visualize the location of the incision, which is made in the third or fourth intercostal space. A 5-cm muscle-sparing incision is made in the auscultatory triangle. Caution must be exercised in retracting the posterior fat pad to avoid injury to the nerve, artery, and vein located therein. A soft tissue retractor is placed, and the lung is retracted to visualize the right phrenic nerve.

The pericardium is opened anterior and parallel to the phrenic nerve to expose the atriocaval junction. The heart is exposed inferiorly to the diaphragm. Pericardial stay sutures in the lateral edges are anchored posteriorly through the skin. The space between the right pulmonary artery and the right superior pulmonary vein is dissected bluntly. A second 10-mm port is created for direct placement of a specially designed dissector (GlidePath, Atri-Cure). The dissector is introduced lateral to the inferior vena cava and advanced into the oblique sinus and swept medially behind the right pulmonary veins. The superior vena cava is retracted medially to expose the right pulmonary artery. The dissector hinge is engaged, which advances the tip into the space between the right superior

FIGURE 87-15 ■ Incision and port sites for minimally invasive pulmonary vein isolation procedure.

pulmonary vein and the right pulmonary artery. The dissector is articulated in the opposite direction and removed after grasping the GlidePath hood to allow guidance of the bipolar RF clamp into the same space. The plastic hood is attached to the bipolar RF clamp (Isolator, Atri-Cure), and the clamp is closed and inserted into the chest through the same port site. The clamp is then opened and advanced to position the jaws around the pulmonary veins, being guided by the previously placed plastic GlidePath hood. We routinely establish baseline pacing thresholds from each of the pulmonary veins before ablation. Two ablations are performed, the second after a small advancement of the clamp onto the atrium. Each ablation is made after assurance that the clamp is on the atrial cuff and not the pulmonary veins proper.

After ablation, conduction block is confirmed by pacing from each of the pulmonary veins. Additional ablations are created until conduction block is achieved. The clamp is removed, the pericardium is reapproximated, an appropriate drain is placed, and the wound is closed.

The patient is then repositioned with the left side up. The left arm is supported superiorly to expose the axilla. A 10-mm port is placed in the sixth intercostal space in the midaxillary line (slightly more posterior than the port on the right side), and a working incision is made in the third intercostal space under direct visualization. The pericardium is initially opened posterior to the phrenic nerve to expose the left pulmonary artery and then widely opened for device access, with caution exercised to preserve the phrenic nerve. Pericardial stay sutures are placed posteriorly and brought through the skin. The ligament of Marshall is divided by electrocautery, and the space between the left pulmonary artery and left superior pulmonary vein is bluntly dissected. The dissector is introduced through a second 10-mm port placed posterior to the first port. The dissector is positioned into the

FIGURE 87-16 ■ AtriClip device. (From Emmert MY, Puippe G, Baumüller S, et al: Safe, effective and durable epicardial left atrial appendage clip occlusion in patients with atrial fibrillation undergoing cardiac surgery: first long-term results from a prospective device trial. *Eur J Cardiothorac Surg* 45:126–131, 2014.)

space below the left inferior pulmonary vein and then articulated to swing the tip into the space between the left superior pulmonary vein and the left pulmonary artery. The clamp is similarly brought into the same space by guidance with the plastic hood as on the right side. Ablation of the pulmonary veins is done after baseline pacing thresholds are recorded, with confirmation of conduction block after ablation.

The left atrial appendage is then removed for the reduction of thromboembolic risk. This is done using an atraumatic clip (AtriClip, AtriCure) (Fig. 87-16). This is potentially safer than using a stapler and has better outcomes in terms of completely excluding the left atrial appendage. A multicenter feasibility study demonstrated no adverse events related to the device, and 60 of 61 patients (98.4%) had successful left atrial appendage exclusion, based on results of computed tomography angiography or transesophageal echocardiography, at 3 months.¹³⁹ In a study prospectively evaluating the long-term safety and efficacy of the AtriClip, serial computed tomographic scans showed stable clip positioning without left atrial appendage reperfusion with a follow-up of 3.5 ± 0.5 years. In addition, at 36 months follow-up, no intracardiac thrombi or embolic strokes had occurred.¹⁴⁰

The pericardium is reapproximated with a drain placed, and the left-sided wounds are closed. Patients typically stay in the hospital for 2 or 3 days for drain removal and arrhythmia monitoring.

Surgical Results: Other Atrial Fibrillation Procedures

The performance of only a left atrial lesion set for the treatment of AF is supported by studies showing that most paroxysmal AF originates from around the pulmonary veins and posterior left atrium.^{29,33} However, the surgical treatment of AF by a left atrial lesion set alone has had lower success rates than with the biatrial Cox-Maze lesion set. Intraoperative mapping studies of patients undergoing surgical treatment of AF showed a distinct region of stable dominant frequency, which is indicative of the area of origin of the arrhythmia, in the

left atrium only 30% of the time. The dominant frequency was located in the right atrium 12% of the time. Most important, the location of dominant frequency moved during the recording period in almost half of the patients.²⁶ Therefore, it is not surprising that interventions with limited lesion sets, particularly pulmonary vein isolation alone, do not have the same results as the complete Cox-Maze lesion set.

Surgical pulmonary vein isolation has been shown to be superior to catheter ablation in patients with left atrial dilation and hypertension or where previous catheter ablation has failed. The FAST trial was a multicenter randomized trial that compared 63 patients who received linear antral pulmonary vein isolation by way of catheter ablation and 61 patients who received bipolar RF pulmonary vein isolation and ganglionated plexi ablation. At 1 year, freedom from left atrial arrhythmias greater than 30 seconds evaluated by a 7-day Holter was 66% for surgical ablation and 37% for catheter ablation ($P = 0.002$).¹⁴¹

A well-known complication of performing only the left atrial lesions is postoperative atrial flutter. In a group of 50 patients described by Golovchiner and colleagues from Tel Aviv, 13% of patients experienced postoperative atrial flutter at a follow-up of only 15 months. Left atrial flutter was present in four of six.¹⁴² In a series from Japan, 5 of 24 patients (21%) experienced recurrent atrial flutter or tachycardia after a left-sided procedure with follow-up of 36.9 ± 14.1 months.¹²⁹

The results with left atrial ablation sets have been variable (cure rates 21% to 95%) and are dependent on the precise lesion set, technology used, and patient population. A randomized trial conducted with patients undergoing mitral valve surgery evaluated whether addition of RF ablation on the left atrium was different from mitral valve surgery alone.¹⁴³ Of 101 patients randomized to undergo mitral valve surgery with or without RF ablation, 99 patients eventually met criteria; 45 were evaluated who had RF ablation versus 44 who had valve surgery alone ($P < 0.001$). At 12 months of follow-up, 44% of those undergoing concomitant RF ablation were in sinus rhythm compared with only 5% of those who had mitral valve surgery alone. Although this was significantly better than no ablation at all, this success rate was much lower than has been reported with the Cox-Maze procedure in patients with mitral valve disease.¹⁴⁴

In a meta-analysis of surgical ablative treatments for AF, Barnett and Ad¹⁴⁵ evaluated 69 studies to assess differences in survival and freedom from AF. These studies included multiple types of energy devices and interventions for lone AF as well as concomitant procedures. Compared with control patients, those undergoing surgical ablation had significantly greater freedom from AF at 2 years ($84 \pm 6\%$ vs. $40 \pm 22\%$, $P = 0.001$); freedom from AF at 2 years was also significantly better in patients who had biatrial ablations ($86 \pm 5\%$ vs. $75 \pm 2\%$, $P = 0.001$). These results support a strategy of doing a more complete ablation set (biatrial) when possible, but a more limited lesion set is superior to no intervention for patients with AF.

The results of pulmonary vein isolation alone have been better in patients who have lone AF than in those undergoing concomitant cardiac surgery. In the series by

Wolf and coworkers,¹³¹ 27 patients with AF (18 paroxysmal, 4 persistent, and 5 permanent) underwent video-assisted bilateral pulmonary vein isolation and left atrial appendage exclusion for AF; 91% of patients were free from AF without antiarrhythmias postoperatively. In a more recent series with longer follow-up, Edgerton and coworkers¹⁴⁶ described 57 patients with AF undergoing pulmonary vein isolation plus ablation of the ganglionic plexi. Most patients were observed with prolonged monitoring. In 39 patients with paroxysmal AF, the freedom from AF at 6 months was 82%, and antiarrhythmic medications were discontinued in 74%. In patients with persistent and long-standing AF, the success rate at 6 months was only 56%, and antiarrhythmic medications were discontinued in only 39%.

McClelland and colleagues¹³⁵ described 21 patients undergoing pulmonary vein isolation with ganglionic plexi ablation. Procedural success was defined as freedom from AF and drugs at 1 year. In patients with paroxysmal or persistent AF, 88% of patients had a successful procedure. However, in patients with long-standing AF, only 25% had a successful outcome with pulmonary vein isolation alone.¹³⁶ In our pulmonary vein isolation experience at Washington University with 43 patients, we have had similar results. Patients have been observed with 24-hour Holter monitoring at 3, 6, and 12 months. Our mean follow-up was 24 ± 37 months. In patients with lone paroxysmal AF, the cure rate was 78%, with 67% both free from AF and off antiarrhythmic drugs. However, in patients with persistent or long-standing AF, the cure rate has been only 38%.

The results with endoscopic microwave pulmonary vein isolation have been worse. This is likely because this technology is not capable of creating reliable transmural lesions on the beating heart.¹⁴⁷ In a group of 50 patients of whom the majority had paroxysmal AF, less than half of the patients were free from AF or reintervention at a mean follow-up of only 7.6 months.¹⁴⁸ In a follow-up report that included 100 patients, the late results were even worse. Only 42% of patients were in sinus rhythm at last follow-up. Although totally thoracoscopic surgical ablation with the microwave device was technically feasible, the clinical results were poor, with no demonstrated electrical isolation of the pulmonary veins and poor long-term cure of AF.¹⁴² Because of these poor results, microwave ablation technology is no longer available.

In our experience, the results with pulmonary vein isolation have been worse in patients undergoing concomitant cardiac procedures than in those undergoing AF intervention alone. At Washington University, 23 patients with AF (12 with paroxysmal AF, 11 with permanent AF) underwent pulmonary vein isolation during concomitant mitral valve surgery or coronary revascularization. The average duration of AF in 12 patients was 6.7 ± 14.2 years. At a mean follow-up of 57 ± 37 months, only 50% of patients were free from AF.¹²⁰

In a series reported by Gaita and colleagues,¹²² 105 patients undergoing AF and valve surgery were randomly assigned to three groups: left atrial ablation by two different patterns or pulmonary vein isolation alone. The freedom from AF at last follow-up was only 29% in the pulmonary vein isolation group versus 76% in those who

had more extensive left atrial lesions. In another series, a group of 101 patients underwent pulmonary vein isolation with cryoablation in addition to mitral valve surgery; the freedom from AF at last follow-up was only 53%.¹⁴⁹ Only 25% of patients were able to maintain sinus rhythm without antiarrhythmic drugs. In a study from Japan, 66 patients with chronic AF and mitral valve disease underwent pulmonary vein cryoablation. Normal sinus rhythm was seen in only 61% of patients at late follow-up, and antiarrhythmic drugs were discontinued in 17% of patients.¹³² These reports of pulmonary vein isolation compare unfavorably with the more than 80% freedom from AF at late follow-up seen in mitral valve patients undergoing the Cox-Maze IV procedure at our institution.¹⁵⁰ However, a limited lesion set may have merit in selected patients, as reported results are better than no intervention at all. Certainly, there are groups of patients who are cured with these methods; continued investigation is needed to identify which factors ultimately determine efficacy in each particular group of patients.

Future Surgical Treatments for Atrial Fibrillation

As surgical techniques and technology have advanced, there has been an increasing trend toward the creation of minimally invasive approaches. Increasingly, groups including our own, are performing ablations through smaller incisions with the aid of thoracoscopic video assistance in properly selected patients. Several groups have started performing epicardial ablations with the aid of suction-based RF and cryoablation probes that can be placed through thoracoscopic ports. Historically, these probes do not achieve the same degree of transmural ablation achieved with bipolar RF clamps. Others have attempted to solve this problem using a "hybrid" approach, which uses a combination of endocardial catheter ablations and epicardial ablations with either bipolar RF clamps and/or unipolar RF devices.^{151,152} This approach can be performed in a single stage or as a dual-stage procedure in which the epicardial ablation is performed first, followed at an interval of time by the endocardial catheter ablation. Both the lesion sets and the approaches using a hybrid method vary greatly from institution to institution, and studies evaluating the hybrid procedure generally have a small number of patients. Although these minimally invasive epicardial and hybrid approaches have yet to match the long-term efficacy of the Cox-Maze IV, they hold promise and require continued clinical investigation to determine their precise role. The ideal surgical treatment for AF would consist of a patient-tailored lesion set using devices that consistently achieve 100% transmural ablation through a minimally invasive approach without the need for cardiopulmonary bypass. However, further development in ablation technology and improvements in preoperative diagnostic tests to better determine the mechanisms of AF in each particular patient are desperately needed.

Conclusions

The introduction of ablation devices has revolutionized the surgical treatment of AF, making these curative

procedures available to a wider population of patients. Whereas there have been few randomized trials comparing the different surgical procedures, conclusions can be drawn from the numerous retrospective series that are available after almost 3 decades of surgical experience. In patients with AF undergoing mitral valve procedures, it is recommended that at least a left atrial Cox-Maze lesion set be performed. This adds only 10 to 15 minutes to the cross-clamp time and cures the majority of patients. At our institution, we prefer a biatrial Cox-Maze IV in these patients because success rates of more than 90% have been reproducible in this population of patients.^{144,150}

In patients undergoing coronary artery bypass grafting, the high success rate of the Cox-Maze lesion set has been documented by our group.¹⁵³ In patients with AF having on-pump coronary bypass grafting, it is recommended that a full biatrial lesion set be performed. However, there have been no randomized comparisons of lesion sets in this population. In patients with AF undergoing off-pump coronary bypass grafting, our policy had been to perform pulmonary vein isolation with removal of the left atrial appendage. However, poor results in patients with long-standing AF led us to abandon this approach in that group.

In patients with lone AF, pulmonary vein isolation alone has had good early results in patients with paroxysmal AF. At our institution, this procedure is performed in patients who have paroxysmal AF and a left atrial size of 4 cm or less. In patients with large atria, we prefer a full Cox-Maze lesion set because of the high incidence of non-pulmonary vein triggers in this population.¹⁵⁴

In patients with persistent or long-standing AF, our policy has been to perform a full biatrial Cox-Maze procedure on cardiopulmonary bypass. This is because of the poor results that have been obtained both by us and others with pulmonary vein isolation alone. With the full Cox-Maze IV procedure, success rates in patients with persistent or long-standing AF have been 91% at 1 year, with all antiarrhythmic drugs discontinued in 76% of patients.¹⁵⁰ There has been no difference in our success rates with use of the full lesion set in comparing patients with paroxysmal AF and those with persistent, long-standing AF.

INAPPROPRIATE SINUS TACHYCARDIA

Background and Indications

Inappropriate sinus tachycardia is a rare disorder that is characterized by an abnormally elevated heart rate at rest and an exaggerated rate response with physical activity. To be considered for interventional therapy, a patient's symptoms need to be refractory to dietary modification and medical management. Inappropriate sinus tachycardia was originally described in 1979, but it has only recently been accepted as a medical condition. Patients suffering from this debilitating condition are typically young women. Inappropriate sinus tachycardia is thought to be the result of enhanced automaticity of the sinoatrial node or hypersensitivity to β -adrenergic stimulation. The sinus node impulse may have a multifocal origin, and early activation sites can shift within the sinus node

complex in response to autonomic influences. The first-line treatment is medical therapy with beta blockers or calcium channel blockers.

In patients for whom medical management fails, catheter or surgical ablation is the next therapeutic option. The efficacy of catheter ablation remains controversial. Reported series are small, and there have been a high percentage of failures at long-term follow-up.^{155,156} This has led many centers to abandon a catheter-based approach. Results with surgical intervention have been better but still leave room for improvement.

Surgical Technique: Superior Right Atrial Isolation

At our center, 10 consecutive patients with inappropriate sinus tachycardia have undergone surgery for this arrhythmia. The first seven patients underwent median sternotomy with cardiopulmonary bypass to ablate or to isolate the sinoatrial node; in the last three patients, a minimally invasive technique developed at our institution was performed.¹⁵⁷ In these latter patients, the sinoatrial node was isolated by bipolar RF ablation through a small inframammary incision, without the use of cardiopulmonary bypass (Fig. 87-17). Isolation and ablation of the sinoatrial node are done through a right 6-cm mini-thoracotomy. Intraoperatively, intravenous isoproterenol is administered to create sinus tachycardia with rates of 150 to 180 beats per minute. A large cuff of right atrium adjoining the junction of the superior vena cava is isolated from the body of the right atrium with a bipolar RF ablation device. Three sequential circumferential ablations are performed, and isolation is confirmed with pacing and by observing a significant blunting in response to intravenous administration of isoproterenol. Bipolar pacing above and below the ablation line confirms that the sinoatrial node and surrounding atrium are isolated from the remainder of the heart.

Surgical Results

Two reports with traditional cardiopulmonary bypass demonstrated complications requiring pacemaker placement

FIGURE 87-17 ■ Position of the bipolar radiofrequency clamp (Isolator, AtriCure) used to isolate the sinoatrial node and surrounding right atrial tissue in the minimally invasive ablation for inappropriate sinus tachycardia. (From Kreisel D, Bailey M, Lindsay B, et al: A minimally invasive surgical treatment for inappropriate sinus tachycardia. *J Thorac Cardiovasc Surg* 130(2):598-599, 2005.)

and development of new supraventricular tachycardia from ectopic foci.^{158,159} In our experience, after a mean follow-up of 7.1 ± 5.7 years, there was no evidence of inappropriate sinus tachycardia recurrence; however, four patients required pacemaker implantation for symptomatic bradycardia and a single patient developed ectopic atrial tachycardia. One patient still experienced palpitations. Four patients experienced complete relief from their cardiac symptoms.¹⁵⁷

Conclusions

Surgical isolation of the sinoatrial node for medically refractory inappropriate sinus tachycardia has acceptable long-term success in preventing recurrence. However, more than half of patients have required pacemaker implantation or have had recurrent symptoms. Less invasive surgical techniques make this a more attractive option for patients with inappropriate sinus tachycardia who have failed medical therapy.

VENTRICULAR TACHYCARDIA

Background

The success of implantable cardioverter-defibrillators (ICDs) and catheter ablation has dramatically diminished the referral of patients with ventricular arrhythmias (ventricular tachycardia) for surgery. However, it is critical that surgeons understand the historically important role of surgery and the present indications for surgical management of ventricular tachycardia. Although ICDs have improved survival by preventing sudden death, they fail to treat the underlying arrhythmogenic substrate. The frequent discharges can impair quality of life.¹⁶⁰ In addition, a population of patients surviving myocardial infarction with ventricular aneurysms, akinetic segments, and ischemic cardiomyopathies develop ventricular arrhythmias and require surgical intervention for treatment of congestive heart failure or coronary artery disease. These patients greatly benefit from concomitant surgery for their ventricular tachycardia.

Historical Aspects of Surgery for Ventricular Tachycardia

In 1961, Estes and Izlar described some patients who underwent successful treatment of ventricular tachycardia with surgical sympathectomy. In the late 1960s, it became apparent that myocardial ischemia initiated many ventricular arrhythmias and that they were related to areas of infarction and scar.¹⁶¹ Two surgical approaches were developed to address this problem: infarctectomy and coronary artery bypass grafting (CABG).^{162,163} Unfortunately, these initial approaches for the surgical treatment of ventricular tachycardia had high mortality rates and relatively poor long-term success. They failed because they were not based on an understanding of the mechanisms involved in ischemic ventricular tachycardia.¹⁶⁴

Improved understanding of these mechanisms during the 1970s led to new surgical approaches. Wellens and

others introduced cardiac mapping techniques that for the first time were able to precisely identify myocardial activation during dysrhythmias.¹⁶⁵⁻¹⁶⁸ Ventricular tachycardia was found to be a reentrant arrhythmia, able to be initiated in the electrophysiology laboratory. It became apparent that ventricular tachycardia often arose from the border zone between infarcted and normal myocardium and that the reentrant circuit was often subendocardial in origin.¹⁶⁹⁻¹⁷³ This led to surgical techniques that were guided by both preoperative and intraoperative electrophysiologic studies.

The first directed surgical cure of refractory ventricular tachycardia was reported in 1975.¹⁶⁷ The patient was a 54-year-old man who presented with refractory ventricular tachycardia after two myocardial infarctions. Epicardial mapping was used to localize the site of earliest epicardial activity to the margin of the aneurysm. Subsequent resection of this area abolished the ventricular tachycardia. In 1978, Guiraudon introduced the encircling endocardial ventriculotomy, an operation designed to isolate the entire border zone from normal myocardium.¹⁷⁴ A near-transmural incision was made from the endocardial surface of the left ventricle down to the epicardial surface (Fig. 87-18). Although this technique met with clinical success, it caused significant ventricular dysfunction. In 1979, Harken and colleagues¹⁷⁵ from the University of Pennsylvania introduced a new technique involving endomyocardial resection directed by intraoperative mapping in 12 patients. They reported 1 operative mortality, with the remaining 11 patients having no recurrent arrhythmias at 1 year. In 1982, Moran¹⁷⁶ modified the endomyocardial resection with an extended resection of all visible scar, which obviated the need for intraoperative mapping (Fig. 87-19). These new procedures resulted in operative mortalities of between 10% and 20%. The success rates improved in some series to

FIGURE 87-18 ■ Encircling endocardial ventriculotomy. LA, Left atrium; LV, left ventricle; MPA, main pulmonary artery. (From Guiraudon G, Fontaine G, Frank R, et al: Encircling endocardial ventriculotomy: a new surgical treatment for life-threatening ventricular tachycardias resistant to medical treatment following myocardial infarction. *Ann Thorac Surg* 26:438-444, 1978.)

FIGURE 87-19 ■ Endocardial resection procedure. LA, Left atrium; LAD, left anterior descending coronary artery; LV, left ventricle; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle. (From Moran JM, Kehoe RF, Loeb JM, et al: Extended endocardial resection for the treatment of ventricular tachycardia and ventricular fibrillation. *Ann Thorac Surg* 34:538–552, 1982.)

more than 70%, and 5-year survival was approximately 60%.¹⁷⁷⁻¹⁸¹ Subsequently, surgical experience revealed that intraoperative mapping was not necessary to achieve good results if an extended endomyocardial resection was performed. When examining approximately 500 patients having either map-guided or non-guided extended resections, Hargrove and Miller¹⁸² determined that the number of patients whose arrhythmias are inducible at the postoperative electrophysiologic study was not significantly different between groups.

With the introduction of the ICD into clinical practice, referrals of patients for ventricular tachycardia surgery decreased markedly. With a new generation of electrophysiologists and cardiac surgeons who are largely unfamiliar with ventricular tachycardia surgery, many physicians now overlook the role that surgery continues to play in selected patients. The following two subsections discuss indications and techniques for the surgical treatment of ventricular tachycardia in the ICD era.

Surgical Indications for Ventricular Tachycardia

A number of important points need to be emphasized about surgical options for ventricular tachycardia. First, surgical mortality in the ICD era has been significantly lower than that historically reported in the early clinical experience with direct ventricular tachycardia surgery. This is because high-risk patients (i.e., poor left ventricular function, no discrete aneurysm, polymorphic ventricular tachycardia) are no longer referred for surgery but are preferentially treated with ICDs. In a series of patients reported from the University of Virginia and from our institution, the hospital mortality rate was 4.9% and surgical success rates were above 90%.¹⁸³

From 1988 to 2008, the Washington University experience included 74 patients.¹⁸⁴ During the last 10 years of this study period, 11 patients underwent direct ventricular tachycardia surgery with no operative mortality. During this time, the median hospital length of stay was 11 days. Seventy-three percent of patients (8 of 11) had no recurrence of their ventricular tachycardia at a mean follow-up of 5.8 years, and there were no late deaths in this group because of the liberal use of adjunctive ICD therapy. The overall survival of the group during the 20-year study period was excellent, with a 5-year survival of 65%. Thus, in properly selected patients, a low operative mortality rate can be expected, with good late results.

A second important point and an advantage of surgery is that the underlying left ventricular dysfunction can be addressed. This is not the case with catheter ablation, which eliminates only the arrhythmogenic substrate. Furthermore, coronary bypass grafting, left ventricular reconstruction or remodeling, and mitral valve repair can have a significant impact on late survival in appropriate patients.^{185,186} In patients who are referred for surgery for left ventricular dysfunction, it is critical that these patients be offered a concomitant procedure to treat the ventricular tachycardia, when indicated, because of the excellent success rates of preventing recurrent ventricular tachycardia.^{185,186} Surgery can improve the patient's quality of life by decreasing the number of defibrillator shocks.

Finally, ventricular tachycardia surgery can play a role in patients who are receiving frequent discharges from their device. Quality of life of these patients is poor.^{160,187} In patients who have failed catheter ablation or are poor candidates for this procedure, surgery can play an important role if the patients have an appropriate substrate. The different procedures for ventricular tachycardia are discussed in the following section.

Surgical Techniques for Ventricular Tachycardia

Revascularization

Surgical coronary revascularization (CABG) alone has not been highly effective at treating ventricular tachycardia.¹⁸⁸⁻¹⁹⁰ However, evidence suggests that when ischemia is the primary trigger for ventricular arrhythmias, CABG can alter the arrhythmic substrate in selected patients to reduce ventricular arrhythmias.^{191,192} Several groups have documented that 40% to 60% of patients undergoing CABG with a preoperative clinical history of ventricular arrhythmias or fibrillation had no inducible ventricular arrhythmias at postoperative electrophysiologic testing.^{189,190} Lee and colleagues demonstrated that only 25% of patients after CABG and ICD implantation for preoperative ventricular arrhythmias had inducible arrhythmias postoperatively.¹⁹³ However, in most patients with chronic ischemic ventricular tachycardia, the results of CABG have been too unpredictable, and most patients require concomitant ICD therapy. In patients with poor left ventricular function, ICDs play a role even when those patients have no history of ventricular tachycardia. The Multicenter Automatic Defibrillator Implantation

Trial II (MADIT II) found that prophylactic ICD implantation improved survival in patients with prior myocardial infarction and poor left ventricular function (left ventricular ejection fraction < 0.30).¹⁹⁴

In patients with ischemic ventricular tachycardia, the only candidates for CABG alone are patients who have significant coronary artery disease, who have no ventricular dilation or aneurysm, and who suffer from documented exercise- or ischemia-induced ventricular arrhythmias. Postoperative exercise testing and electrophysiologic studies are used to determine whether implantation of an ICD is warranted.

Endocardial Resection

The resection of all visible endocardial scar, a procedure introduced by Harken in 1979, has become the gold standard and the most commonly performed operation for ventricular tachycardia.¹⁷⁵ The amount of ventricular tissue involved or its location near the posterior papillary muscle may limit a complete resection. In these cases, alternative ablation techniques are used either adjunctively or as the sole therapy. Although groups have reported use of energy sources such as laser, RF ablation, and microwave, the most commonly used and well-studied ablation technique is cryoablation. Popularized in the 1980s, the cryoablation probe is applied to the scar and typically cooled to -60°C for 2 or 3 minutes, resulting in lesions 2 to 3 cm in depth.

Although intraoperative mapping has yielded a wealth of information into the mechanisms of ventricular arrhythmias, its clinical practicality and questionable added efficacy to ventricular tachycardia surgery have prevented its widespread adoption. Virtually all surgeons have adopted a technique of resecting all visible endocardial scars without the use of intraoperative mapping.

A retrospective review of 74 patients who underwent an endocardial resection procedure (ERP) with adjunctive cryotherapy for ventricular arrhythmias from 1986

to 2007 was performed at Barnes-Jewish Hospital at Washington University in St. Louis. The mean age was 57 ± 14 years, and 81% of patients were male. One quarter of patients were in New York Heart Association class III or class IV heart failure, and the mean left ventricular ejection fraction was $34\% \pm 9\%$. Ninety-two percent of patients underwent ERP with a concomitant procedure, and 8% underwent ERP alone. The spectrum of procedures included ERP plus left ventricular aneurysm repair (26%), ERP plus CABG (5%), ERP plus CABG plus left ventricular aneurysm repair (46%), and ERP plus left ventricular aneurysm plus other cardiac procedure (15%). The overall operative mortality rate was 15%, with a median intensive care unit length of stay of 4 days and a median hospital length of stay of 12 days. As stated previously, there was no operative mortality during the last 10 years of our experience. Late follow-up was completed in 89% of patients. A Kaplan-Meier survival analysis was performed, and absolute survival for all patients in this series was 74% at 1 year and 65% at 5 years. Eighty-eight percent of the cases were performed during the first decade (1986 to 1996) and the remaining cases during the next decade (1997 to 2007), reflecting the diminishing role of surgical management in this disease. Since 2007, only three additional ERPs have been performed (Fig. 87-20).

Left Ventricular Reconstruction

In 1985, Vincent Dor described a surgical technique to restore the dilated left ventricle in patients with ischemic cardiomyopathy or ventricular aneurysms to its normal elliptical shape by reducing the volume of the ventricle.^{195,196} The Dor procedure uses an endoventricular circular patch to reduce ventricular volume, which subsequently reduces wall tension and ischemia. Good surgical candidates for left ventricular reconstruction typically present with heart failure (left ventricular ejection fraction $< 40\%$), coronary artery disease, large areas of myocardial akinesis (ventricular dilation), or a

FIGURE 87-20 ■ Washington University School of Medicine/Barnes-Jewish Hospital experience with ventricular tachycardia surgery.

left ventricular aneurysm. These patients commonly have associated ventricular arrhythmias. Currently, Dor emphasizes the importance of complete revascularization (CABG), repair of any mitral disease, and endocardial resection with cryoablation at the same setting. A more complete description of the Dor procedure and its modifications, including technical considerations, can be found in [Chapter 100](#).

In 2004, Maxey and colleagues demonstrated that the Dor procedure restores the left ventricle's geometry, resulting in a mean ejection fraction increase of 12.5%.¹⁹⁷ Ventricular function continues to improve during the patient's lifetime. The RESTORE group experience examined a registry of 1198 postinfarction patients between 1998 and 2003 who underwent left ventricular restoration and found that 5-year freedom from hospital readmission for congestive heart failure was 78%. In addition, 67% of patients were assigned to class III or class IV preoperatively; 85% were assigned to class I or class II postoperatively.¹⁸⁵

Several groups have demonstrated that the triggers for ventricular arrhythmias occur at the scar border zone in patients with ischemic cardiomyopathy.¹⁶⁵⁻¹⁶⁸ Thus, the Dor procedure addresses ventricular arrhythmias by removing the anatomic substrate during resection of the postinfarction scar or aneurysm. In 1994, Dor and associates¹⁹⁶ reported a 90% freedom from inducible ventricular tachycardia at 1 year after endocardial resection and left ventricle reconstruction in 106 patients. In 2004, Mickleborough and colleagues reported long-term outcomes after left ventricular reconstruction and coronary revascularization for patients with hypokinesis or akinesis and coronary artery disease with poor left ventricular function. Results demonstrated that operative survivors had freedom from ventricular tachycardia and sudden death at 1 year, 5 years, and 10 years of 99%, 97%, and 94%, respectively.¹⁹⁸

In spite of the excellent results previously mentioned, the efficacy of left ventricular restoration alone for the treatment of ventricular tachycardia has been controversial. The Cleveland Clinic experience illustrated the relative lack of efficacy of the Dor procedure alone without endocardial resection surgery.¹⁹⁹ In this series, 48 of 113 patients (42%) who had a postoperative electrophysiology study had inducible ventricular tachycardia after the Dor procedure. Furthermore, in patients with an ICD, 15% had either sudden cardiac death or appropriate shocks. With early electrophysiology study, ICD implantation, or both, the overall incidence of sudden cardiac death was less than 1%. In 2004, DiDonato and associates demonstrated in 382 patients that left ventricular restoration with endocardial resection reduced the inducible ventricular tachycardia from 41% to 8%, suggesting that many patients may not need a postoperative ICD.¹⁸⁶

Because of the high lethality of ventricular tachyarrhythmias in patients in whom surgery is not curative, it is generally recommended that all patients after the Dor procedure undergo electrophysiology study or implantation of an ICD if they have had a history of ventricular arrhythmias or inducible ventricular tachycardia preoperatively.

Cardiac Assist Devices and Heart Transplantation

In rare cases, patients present with uncontrolled ventricular arrhythmias refractory to conventional surgical, ICD, or medical therapy. Typically, these patients have an end-stage cardiomyopathy resulting in incessant ventricular tachycardia. If the patients are not amenable to conventional cardiac revascularization or other procedures, these malignant arrhythmias may be effectively palliated with a cardiac assist device, either as a bridge to transplantation or as destination therapy.²⁰⁰⁻²⁰² The cardiac assist device effectively reduces myocardial oxygen demand and can decrease the incidence of ischemia-induced arrhythmias.²⁰³

Conclusions

ICDs and catheter ablation have significantly reduced the role of surgery in the treatment of ventricular arrhythmias. When indicated, however, current surgical techniques can be quite successful. The surgical approach should be individualized to each patient. The current indications for surgery include the following: (1) In patients who have ischemic ventricular tachycardia requiring revascularization and who have poor left ventricular function and no significant wall thinning, the recommended treatment is CABG and ICD placement. If significant wall thinning or a discrete aneurysm is present, ventricular remodeling, extended endomyocardial resection, and cryoablation should be performed. (2) Surgery for ventricular tachycardia should be considered for patients suffering from frequent ICD discharges that are poorly tolerated and have an amenable anatomic substrate. In the presence of frequent ICD shocks with a discrete left ventricular aneurysm or wall thinning, ventricular remodeling, extended endomyocardial resection, and cryoablation should be considered.

CABG versus PCI

CONCLUSION

Coronary artery bypass grafting (CABG) is among the most important surgical procedures in the history of medicine. Arguably, no other operation has prolonged more lives, provided more symptom relief, and been more thoroughly investigated. CABG has been the most common procedure of adult cardiac surgery, but its future is increasingly threatened by medical and percutaneous alternatives. However, CABG is evolving with less invasive options, better postoperative care, and refined medical adjuncts. This treatment strategy remains the

most durable means of revascularization for patients with coronary artery disease (CAD) and even more so for patients with diabetes and multivessel CAD. This chapter outlines the history, anatomic considerations, indications, techniques, postoperative care, and results of the modern CABG procedure. Other, complementary chapters in this book cover cardiac anatomy, the coronary circulation, cardiopulmonary bypass, myocardial protection, bypass conduits, off-pump grafting techniques, reoperations, combined procedures, and general postoperative care.

BACKGROUND

History

The initial development of CABG is credited to Dr. Alexis Carrel, who more than a century ago understood the association between angina pectoris and coronary stenosis.¹ In a canine model, Carrel anastomosed a carotid artery segment between the descending thoracic aorta and the left coronary artery. Carrel received the Nobel Prize in Physiology and Medicine for this work in 1912 (Fig. 88-1).¹ Despite this major advance in medical science, the lack of technology to support the heart remained a major hurdle toward the clinical implementation of Carrel's techniques. That surgical roadblock persisted for several decades, until Carrel collaborated with aviator Charles Lindbergh in the 1930s in hopes of developing the world's first heart-lung machine.² Although unsuccessful, their work added to the medical knowledge of the time.

In the late 1940s, Montreal surgeon Arthur Vineberg began implanting the left internal thoracic artery (LITA) onto the anterior myocardial territory in patients with severe angina.³ The Vineberg procedure met with variable success, although many patients experienced symptomatic improvement.⁴ In 1958, Johns Hopkins-trained William Longmire reported on his series of five patients treated with coronary artery endarterectomy, without the use of cardiopulmonary bypass (CPB).⁵ Longmire was likely the first to perform a direct internal thoracic artery (ITA) to coronary artery anastomosis as a consequence of damage to the right coronary artery during one of his endarterectomy procedures.⁶

At approximately the same time, a number of surgeons across the globe were reporting their early experiences

with CABG. In 1962, Sabiston performed the first planned saphenous vein bypass operation at Duke University.⁷ In 1964, Kolesov grafted the LITA to the left anterior descending (LAD) artery, without CPB,⁸ and DeBakey and Garrett reported aortocoronary saphenous vein grafting (SVG).⁹ The world's first CABG program started 3 years later in Cleveland, as Favaloro and Effler began to routinely use reversed saphenous veins for aortocoronary grafting.¹⁰ LITA grafting to the LAD was introduced in the Western world by Green in 1968,¹¹ sequential grafting by Flemming in 1971,¹² bilateral internal thoracic grafting by Kay in 1972,¹³ and the use of radial artery grafts described by Carpentier in 1973 and revived by Acar in 1989.^{14,15}

In the 1970s CABG flourished as the sole therapy for CAD. Several randomized trials—namely, the Coronary Artery Surgery Study (CASS),¹⁶ the Veterans Administration Coronary Artery Bypass Trial,¹⁷ and the European Coronary Artery Bypass Trial¹⁸—were conducted and would lay the foundation for surgical indications. In the modern era of CABG surgery, the prototypical patient is older, has significantly more comorbidities, and is more likely to have undergone percutaneous coronary intervention (PCI) with a drug-eluting stent.¹⁹ However, several multicenter studies comparing CABG with current stent therapy—namely, the Synergy between Percutaneous Coronary Intervention with Taxus and Cardiac Surgery (SYNTAX),²⁰ Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM),²¹ and Coronary Artery Revascularization in Diabetes (CARDia)²² trials—have clearly demonstrated the superiority of CABG when specific patient characteristics, such as diabetes, and coronary anatomy, such as involvement of all three coronary vessels, are taken into account.

FIGURE 88-1 ■ Advances in the surgical treatment of coronary artery disease. CABG, Coronary artery bypass grafting; CASS, Coronary Artery Surgery Study; ITA, internal thoracic artery; LAD, left anterior descending coronary (artery); LITA, left internal thoracic artery; VA, Veterans Administration Coronary Artery Bypass Surgery Cooperative Study.

Anatomic Considerations

Coronary artery anatomy and size vary widely among individuals. In the absence of CAD, coronary perfusion matches myocardial demand because capillary oxygen extraction is relatively fixed.²³ During exercise, coronary perfusion increases three- to fourfold as a result of vasodilation of coronary arteries and arterioles and from recruitment of additional capillaries.²⁴

In the setting of symptomatic CAD, compensatory physiologic processes are insufficient to provide adequate myocardial perfusion. The effect is either *supply ischemia*, responsible for myocardial infarction (MI) and most episodes of unstable angina, or *demand ischemia*, where coronary blood flow is insufficient during periods of increased myocardial demands from exercise, tachycardia, fever, hypertension, or emotional distress.²⁵ Basal arteriogenesis and collateral formation may be enhanced when new coronary flow patterns and subclinical ischemia develop, but their extent largely depends on the time course of CAD development and is governed by genetic and environmental factors. It is the magnitude of arterial collateralization, of *de novo* arteriolar and capillary development, and dynamic vascular responses that determine the degree of ischemia experienced by a patient. Furthermore, the size and function of the subtended myocardial territory at risk (demand) dictates the degree of ischemia and risk of heart failure in patients with obstructive CAD (supply).

Depending on referral patterns, 40% to 60% of patients who undergo coronary angiography have significant disease involving all three coronary arteries, and 10% to 20% of those patients have stenosis of the left mainstem.²⁶ In patients with single- or double-vessel disease, the most frequently stenosed coronary artery is the right, followed closely by the LAD and least frequently by the circumflex. In some patients, atherosclerosis may be mimicked by myocardial bridging of a coronary artery, which involves a segment of coronary artery completely surrounded by myocardium. Myocardial bridging can result in cardiac ischemia although traditional noninvasive tests are often negative.²⁷

Myocardial hypoperfusion leads to one of four pathophysiologic consequences: stunned myocardium (reversible myocardial dysfunction despite normal/near normal coronary blood flow), hibernating myocardium (reversible myocardial dysfunction with reduced coronary blood flow), nontransmural scar tissue, or transmural scar tissue (irreversible typically nonviable myocardial dysfunction). Patients who describe ischemia on exertion will typically exhibit viable (stunned or hibernating) myocardium, whereas those who describe heart failure symptoms may suffer from irreversible myocardial dysfunction. In addition to clinical evaluation, several contemporary imaging modalities with relatively good sensitivity and specificity are used to further delineate and quantify the proportion of viable myocardium, the most common being nuclear imaging with positron emission tomography (PET) (evaluating viability with glucose uptake of ¹⁸F-fluorodeoxyglucose [FDG]), single photon emission computed tomography (SPECT) (with thallium or technetium radiotracer), dobutamine stress echocardiography (with contrast agents), and dobutamine stress cardiac

magnetic resonance imaging (MRI). With PET, stunned myocardium appears as a hypocontractile segment with normal perfusion and glucose uptake at rest, and hibernating myocardium as a territory with decreased perfusion but preserved glucose uptake.²⁸ Scar tissue, unlikely to benefit from CABG, exhibits both reduced perfusion and glucose uptake, with a milder reduction in nontransmural scars and a severe reduction in transmural scars.

In addition to assessment of angiographically defined stenosis and myocardial viability, technologic advances in interventional cardiology have led to quantitative measurement of coronary blood flow across lesions, and ultra-refined topographic imaging of coronary lesions.^{29,30} Fractional flow reserve values of less than 0.8 (considered significant flow limiting CAD as measured by flow across coronary lesions) has altered management strategies in patients with borderline angiographic CAD resulting in less graft anastomosis at CABG and thus, less on-pump surgery.^{31,32} Alternatively, intravenous ultrasound (IVUS) and optical coherence tomography has improved the resolution and sensitivity of identifying obstructive CAD not traditionally seen on standard angiography.^{31,33} In summary, imaging modalities such as coronary angiography (standard and CT) are obligate adjuncts in defining anatomic coronary artery stenosis and can be further characterized by functional studies such as PET viability, fractional flow reserve, or IVUS. These functional preoperative imaging studies help the cardiac surgeon in determining whether the patient meets indications for CABG and predict the degree of improvement after surgery and outcomes in general.

INDICATIONS FOR OPERATION

The indications for CABG described in this section are based on the 2011 American College of Cardiology/American Heart Association (ACC/AHA) guidelines.³⁴ These updated guidelines include several contemporary multicenter randomized controlled trials comparing CABG to PCI with either first- or second-generation drug-eluting stents, which have become the treatment of choice for PCI.^{35,36} In contrast, previous recommendations were mostly based on historical trials comparing either bare-metal stents or angioplasty alone with CABG.³⁷⁻⁴⁰ With the advancement of less thrombotic stents (i.e., everolimus-eluting stents),⁴¹ minimally invasive CABG options or hybrid operations, and better medical treatment for CAD, it is no surprise that indications for surgical revascularization will be further refined, driven by the constant need to improve patient outcomes.

The pivotal SYNTAX trial randomized 1800 patients with left main or triple-vessel disease to undergo either CABG or PCI (drug-eluting stents).²⁰ The extent of CAD was determined using the SYNTAX score based on severity, location, and extent of coronary stenosis. A low SYNTAX score was defined as less than 22, intermediate as 23 to 32, and high as 33 and above. At 12 months, major adverse cardiac and cerebrovascular events (MACCEs) were significantly higher in the PCI group compared with CABG patients (17.8% vs. 12.4%; $P = 0.002$). This was

mostly accounted for, after post hoc analysis, in patients with higher SYNTAX scores (≥ 33).²⁰ At 3 years, patients with triple-vessel disease and low to intermediate SYNTAX scores (≤ 32) had lower rates of MACCE compared with PCI ($P < 0.004$), whereas patients with left main CAD and SYNTAX scores 33 and higher had lower incidence of MACCE compared with PCI ($P = 0.003$).⁴² Furthermore, because patients with diabetes had higher rates of revascularization in the PCI group compared with CABG, the FREEDOM trial²¹ was conducted to determine whether current PCI therapy (with second-generation drug-eluting stents) or CABG is superior for diabetic patients with multivessel CAD. This randomized controlled trial demonstrated CABG to be superior over PCI in diabetic patients with lower 5-year rates of death and MI; however, stroke rates were slightly higher in CABG patients. Thus, based on the aforementioned historical and latest studies along with the updated ACC/AHA guidelines, the following sections provide detailed anatomic and clinical scenarios for CABG indications.

Clinical Scenarios and CABG Indications

Stable Ischemic Heart Disease

The indications for CABG in the setting of asymptomatic, mild angina, or chronic stable angina are based on the observed survival advantage of CABG over nonsurgical therapy (Table 88-1).^{34,39} Class I indications include the use of CABG to treat significant left main disease ($\geq 50\%$), left main equivalent disease (i.e., proximal stenosis of at least 70% of the proximal LAD and circumflex), triple-vessel disease (especially in patients with left ventricular ejection fraction [LVEF] $< 50\%$ and/or in whom a large area of myocardial ischemia exists), and proximal LAD disease combined with an LVEF between 35% and 50%.³⁴ CABG is also indicated for patients with proximal LAD disease without left ventricular dysfunction, and may be indicated for patients with single- or double-vessel disease not involving the proximal LAD (class IIa).⁴³ Finally, CABG or PCI is indicated in patients with at least one significant coronary artery stenosis with unacceptable angina despite optimal medical therapy (class I) (Table 88-2).^{39,44-46} Recent large studies have demonstrated that stable anginal patients treated with either optimal medical therapy or PCI ($\pm$ CABG) had no significant survival benefit.^{44,47-50} Thus, although these updated guidelines provide a treatment algorithm for CAD patients, the ultimate decision regarding revascularization options should be made between the expert clinician and the well-informed patient.

Acute Coronary Syndromes

Unstable Angina/Non-ST-Segment Elevation Myocardial Infarction. The indication for CABG in patients with unstable angina or non-ST-segment elevation myocardial infarction (NSTEMI) is anatomically identical to that in patients with stable ischemic heart disease.⁴³ This includes patients with significant left main or left main equivalent disease, patients with triple-vessel disease, and

TABLE 88-1 Class I and IIa Indications for CABG Surgery

COR	LOE	Clinical or Anatomic Setting
I	A	One or more significant ($>70\%$) coronary artery stenoses amenable to revascularization and unacceptable angina despite best medical therapy (<i>consider PCI as alternative</i>)
I	B	Unprotected left main disease ($>50\%$)
I	B	Triple-vessel disease with or without proximal LAD artery disease
I	B	Survivors of sudden cardiac death with ischemia-mediated ventricular tachycardia
I	B	Double-vessel disease with proximal LAD artery disease
I	B	Emergency CABG after failed PCI in presence of ongoing ischemia or threatened occlusion with substantial myocardium at risk (without impaired coagulation and without a previous sternotomy); surgical repair of a postinfarction mechanical complication (i.e., septal or free wall rupture)
I	B	Emergency CABG in patients with cardiogenic shock, suitable for CABG irrespective of time interval from MI to onset of shock and time from MI to CABG.
I	C	Patients undergoing noncoronary cardiac surgery with left main disease ($>50\%$) or any other CAD ($>70\%$)
I	C	Heart team approach recommended for unprotected left main disease or complex CAD
IIa	B	CABG over PCI in patients with complex triple-vessel CAD (i.e., SYNTAX > 22)
IIa	B	Double-vessel disease without proximal LAD disease with extensive ischemia
IIa	B	Single-vessel proximal LAD disease with LITA for long-term benefit
IIa	B	CAD with left ventricular ejection fraction 35% to 50%
IIa	B	Hybrid (LITA to LAD artery CABG + PCI for non-LAD arteries) for limitation for CABG (unsuitable conduits) or unfavorable LAD artery for PCI

CABG, Coronary artery bypass grafting; CAD, coronary artery disease; COR, class of recommendation; LAD, left anterior descending; LITA, left internal thoracic artery; LOE, level of evidence; MI, myocardial infarction; PCI, percutaneous coronary intervention.

Derived from 2011 AHA/ACC guidelines for CABG.⁴³

patients with ongoing ischemia not responsive to maximal nonsurgical therapy or failed/unfavorable PCI (see Table 88-1). The major difference between anatomically similar patients presenting with unstable angina or NSTEMI compared with stable CAD is that achieving revascularization in an acute coronary syndrome, a potentially life-threatening scenario, creates a stronger motive in preventing death.⁵¹⁻⁵³ The indication for CABG in this setting is further strengthened by the acuity of presentation, degree of ischemia, and benefit of full revascularization.

ST-Segment Elevation (Q Wave) Myocardial Infarction. Primary PCIs and intravenous thrombolytic therapy have supplanted CABG as the first line of therapy

TABLE 88-2 Pertinent History and Physical Examination Elements for CABG

Preoperative Assessment	Possible Implications	Management
History		
Symptoms		
SHORTNESS OF BREATH		
Orthopnea	Left ventricular dysfunction; right ventricular dysfunction; valve disease	Warrants echocardiography to determine cardiac anatomy
Aggravated with activity	Cardiac ischemia	May warrant more urgent surgery depending on severity of symptoms
Chest pain	Cardiac ischemia	Alert anesthesiologist of possible airway difficulty; arrange for CPAP postoperatively
Poor sleep quality/snoring	Sleep apnea	Assess peripheral and central pulses; brachial-ankle index, echocardiography to assess ascending aortic calcification
Claudication	Peripheral vascular disease	Imaging to determine disease in celiac-mesenteric axis; contraindicates gastroepiploic artery use
Postprandial pain	Mesenteric angina	
Past Medical History		
Diabetes mellitus	Poor wound healing; difficult glycemic control perioperatively	Consider skeletonized harvesting for bilateral internal thoracic arteries
Previous sternal irradiation	Internal thoracic artery damage	May contraindicate use of internal thoracic artery
Previous TIA/amaurosis fugax/stroke	Atherosclerotic disease involving arch vessels	Warrants carotid duplex examination and echocardiography; possible need for CT or MRI angiogram to elucidate disease extent
Raynaud phenomenon	Compromised flow in upper extremity precluding radial artery use	May warrant Doppler examination of the forearm; contraindicates radial artery use in most cases
Past Surgical History		
Lower extremity vein stripping	Lack of greater saphenous vein	Choose alternative conduits
Abdominal laparotomy	Possible contraindication to gastroepiploic artery use	Choose alternative conduits
Medications		
Chronic steroid use	Poor wound healing postoperatively; consider steroid withdrawal postoperatively; difficult glycemic control perioperatively	May contraindicate use of bilateral internal thoracic artery use; ensure postoperative steroid administration and glycemic control
Physical		
Asymmetric brachial blood pressure	Atherosclerotic disease involving arch vessels	Warrants carotid and subclavian duplex examination; contraindicates use of pedicled internal thoracic artery grafts on the ipsilateral side of subclavian stenosis
Increased JVP/peripheral edema	Left ventricular dysfunction; valve disease	Warrants echocardiography to determine cardiac anatomy
Auscultation		
Increased P2	Pulmonary hypertension	Warrants echocardiography to determine cardiac anatomy ± CT chest
Murmur	Concomitant valve disease	Chest radiograph; echocardiography to determine cardiac anatomy
Clubbing	Bronchiectasis; chronic pulmonary hypertension; lung malignancy	

CABG, Coronary artery bypass grafting; CPAP, continuous positive airway pressure; CT, computed tomography; JVP, jugular venous pressure; MRI, magnetic resonance imaging; TIA, transient ischemic attack.

for patients in the acute period of ST-segment elevation myocardial infarction (STEMI).³⁴ As a consequence, ongoing ischemia or cardiogenic shock despite maximal nonsurgical therapy, including intra-aortic balloon pump counterpulsation, currently constitute the main indications for emergency CABG in acute STEMI patients (see Table 88-1).³⁴ Other indications for emergency CABG in the setting of STEMI include failed PCI or thrombolysis and demonstration of a large myocardial territory at risk, in combination with an unsuitable anatomy for PCI, left main coronary stenosis, left ventricular failure with severe coronary stenosis outside the initial infarct area, significant valve disease, life-

threatening ventricular arrhythmias believed to be ischemic in origin (left main or triple-vessel CAD), or a mechanical complication of MI such as severe mitral insufficiency, left ventricular wall rupture, or ventricular septal rupture.³⁴

The timing of CABG after an acute coronary syndrome is controversial. Although early surgery may limit the expansion of the infarct, it runs the risk of reperfusion injury that may lead to a hemorrhagic infarct and scar development. In some cases, such as ongoing ischemia and mechanical complications, CABG cannot be delayed and the availability of mechanical support becomes very important. However, data from the New York State

Cardiac Surgery Registry showed that CABG within 6 hours of a nontransmural infarct or within 3 days of a transmural infarct was independently associated with in-hospital mortality. Therefore, CABG should be delayed for at least 6 hours after a nontransmural infarct and 3 days after a transmural infarct when no clear indication for immediate CABG is present.^{55,56}

Spontaneous Coronary Artery Dissection. One rare form of acute coronary syndrome is spontaneous coronary artery dissection (SCAD), which affects 0.1% to 4% of patients with acute coronary syndromes.⁵⁷ SCAD is a nontraumatic, noniatrogenic separation of the coronary arterial wall by intramural hemorrhage leading to compression of the lumen with intramural hematoma. Typical patients presenting with SCAD include females younger than 50 years without traditional cardiovascular risk factors. Causes of SCAD include pregnancy, connective tissue disorders, systemic inflammatory conditions, coronary artery spasm, and precipitating stress events (intense exercise, emotional stress, labor, or cocaine).⁵⁸ Whereas the mainstay of treatment for stable SCAD patients entails beta blockers and antiplatelets, PCI or surgical revascularization should be considered in patients who have ongoing chest pain, show evidence of ischemia, or are hemodynamically unstable despite maximal medical therapy. Specific indications for CABG follow similar anatomic considerations (i.e., left main, left main equivalent, or triple-vessel disease).^{58,59}

Concomitant Noncoronary Cardiac Surgery

Patients undergoing other forms of cardiac surgery such as valvular repair, where coronary angiography demonstrates either a 50% luminal diameter narrowing of the left main artery or a more than 70% narrowing of any other epicardial coronary artery, should undergo concomitant CABG (class I; evidence C). Furthermore, the LITA is a reasonable conduit choice for bypassing the LAD artery (class IIa), and other conduits, mostly vein grafts, can be used to bypass moderately diseased coronary arteries (>50% narrowing) (class IIa).³⁴

Left Ventricular Dysfunction and Heart Failure

CABG is indicated in patients with left ventricular dysfunction (LVEF 35% to 50%; class IIa and LVEF < 35%; class IIb) and left main or left main equivalent disease, and also in the setting of proximal LAD stenosis with double- or triple-vessel disease.⁶⁰⁻⁶² Despite the increased risk of left ventricular dysfunction on perioperative mortality, the long-term results of CABG in patients with mild to moderate left ventricular dysfunction appear favorable.⁶¹⁻⁶³ It is important to note that patients who have poor left ventricular function and/or congestive heart failure (CHF) symptoms must be evaluated for valvular disease and for objective evidence of hibernating myocardium with a perfusion scan. Despite historical studies demonstrating better outcomes with mild to moderate left ventricular dysfunction, results in patients with advanced left ventricular dysfunction (LVEF < 35%)

treated with CABG are more controversial. The Surgical Treatment for Ischemic Heart Failure (STITCH) trial enrolled patients with an LVEF less than 35% with or without myocardial viability.⁶⁴ The primary endpoint of all-cause mortality did not differ in surgically versus medically treated patients at 5 years follow-up. However, several combined secondary endpoints, including death from any cause and heart failure–related hospitalization, were significantly lower in CABG patients. Thus, in efforts to discriminate a difference in survival, the study will be followed for an additional 5 years.

Life-Threatening Ventricular Arrhythmias and Sudden Cardiac Death

Data describing the benefit of CABG as a treatment for ventricular arrhythmias originate from studies involving survivors of out-of-hospital cardiac arrest. CABG is more effective in treating ventricular fibrillation than ventricular tachycardia, as the latter originates from myocardial scar formation. CABG is also particularly useful in the setting of exercise-induced ventricular arrhythmias,^{65,66} and it has been shown to suppress ventricular arrhythmias in the setting of left main or triple-vessel disease. Alternatively, CABG should not be performed on patients with ventricular tachycardia or evidence of scar. All patients should undergo consultation with an electrophysiology specialist for consideration of insertion of an implantable cardioverter-defibrillator (ICD). Patients with depressed left ventricular function, older age, female sex, and extended CPB runs are more prone to developing life-threatening arrhythmias such that temporary mechanical circulatory support may be justified.^{67,68}

Failed Percutaneous Coronary Intervention

Because of improved PCI techniques, stent technologies, and antiplatelet options, failed PCI requiring emergency CABG is rare, with an incidence of 0.4% to 0.8%.^{69,70} Broad indications for CABG after failed PCI include an acute closure of a coronary vessel (or threatened), vessel dissection, perforation, or malfunction of the PCI equipment (i.e., fractured guidewire). Most patients who undergo emergency CABG exhibit an evolving STEMI, triple-vessel disease, left main disease, cardiogenic shock, or a type C coronary arterial lesion (defined as a lesion with any of the following: diffuse lesion [>2 cm length], inability to protect major side branch, excessive tortuosity, degenerated vein grafts, or total occlusions more than 3 months old).^{69,70} As expected, patients who undergo emergency CABG have increased perioperative morbidity and mortality rates. Independent predictors of worse outcomes include advanced age, depressed left ventricular function, cardiogenic shock, absence of angiographic collaterals, and a prolonged time delay for transfer to the operating room.^{71,72} However, if complete revascularization can be achieved without protracted delay, the long-term outcomes in emergency CABG patients after failed PCI mirror those of elective CABG patients.^{70,73-75} Finally, an off-pump CABG approach for patients in whom PCI failed may be associated with less bleeding requiring

reoperation, less renal failure, and less intra-aortic balloon pump usage.^{76,77}

Previous Coronary Artery Bypass Grafting

Operative risk associated with reoperative CABG is greater than that for the primary operation because of the fact that on reentry there may be damage to patent grafts or other cardiac structures, such as the right ventricle or innominate vein. Coronary identification at reoperation is also more difficult. Given the increased risk, the indications for reoperative CABG largely depend on the degree of symptoms, size of the myocardial territory at risk, concomitant valvular disease, and suitability for PCI.⁷⁸ Current guidelines advocate first, PCI in previous CABG patients refractory to medical therapy (class IIa), followed by redo CABG if disabling angina refractory to maximal medical therapy and PCI occurs (class IIb).⁷⁹ Despite the increased risk, advances in current surgical techniques have significantly narrowed the perioperative risk gap between reoperative and primary CABG with studies demonstrating similar long-term outcomes between redo and primary CABG.

In summary, patients undergoing intervention for CAD should be assessed on a case-by-case basis. After clinical, social, and anatomic patient characteristics are taken into account, the use of a heart team is recommended when the choice of revascularization is not apparent. The heart team may take advantage of a hybrid coronary revascularization strategy by performing LITA to LAD artery grafting and PCI of one or more non-LAD arteries. This approach is reasonable in patients with either limitations to traditional CABG (lack of suitable graft conduits, severely calcified aorta) or an unfavorable LAD artery for PCI (tortuous vessel or chronically occluded artery).³⁴

SURGICAL TECHNIQUE

Preoperative Preparation

In most cases, patients are referred to cardiac surgery for CABG with the diagnosis of myocardial ischemia confirmed via noninvasive testing, coronary angiography, or both. Despite this, a detailed and focused history, physical examination (including determining the functional status of the patient), and review of all tests should be performed to confirm the surgical indication, determine the operative risk, and allow for optimal surgical planning (see [Table 88-2](#)).

History and Physical Examination

Attention must be given to a possible misdiagnosis (especially when symptoms appear out of proportion to the angiographic severity of the coronary stenoses), to comorbid conditions, and to the availability of conduits for revascularization. For example, patients with predominant symptoms of dyspnea may have concomitant valvular disease, cardiomyopathy, or pulmonary hypertension that was missed during preoperative evaluation.

On physical examination, this can be determined by the presence of a murmur, an accentuated P2 indicating pulmonary hypertension, signs of cardiomegaly, and subtle cyanosis or clubbing. Symptoms and signs of CHF should be elicited, because the coexistence of CHF may impact preoperative testing, perioperative medical management, intraoperative planning (with respect, in some cases, to the choice of myocardial protection strategy and the selection of conduits), and short- and long-term prognosis after operation.⁸⁰ Patients with previous mediastinal irradiation should undergo preoperative echocardiography to rule out valve disease, pulmonary function testing, computed tomography (CT) of the chest to assess the degree of aortic calcification, and carotid duplex examination. Patients with a history of peptic ulcer disease should be identified and the use of perioperative nonsteroidal anti-inflammatory agents avoided.

The peripheral vascular examination is of utmost importance. Brachial blood pressure should be measured in both arms to determine hemodynamically significant subclavian artery stenosis. A difference of systolic blood pressure more than 20 mm Hg warrants Doppler examination and may necessitate the use of a free ITA graft or alternate conduit if a subclavian stenosis is confirmed.⁸¹ The lower extremities should be examined for the presence of varicose veins and incisions from previous saphenectomy or peripheral vascular procedures. The patient should also be asked whether sclerotherapy was ever performed. Lower extremity arterial disease is associated with a relative mortality risk of approximately fivefold, regardless of the presence of symptoms.⁸² These patients have the highest incidence of aortic calcification and perioperative stroke, and particular attention must be given to the ascending aorta when assessing the preoperative chest x-ray and reviewing the coronary angiogram.⁸³ In cases where a suspicion exists, CT of the chest is indicated. Documentation of peripheral pulses is important if intra-aortic balloon counterpulsation is to be considered and provides a rapid, albeit imperfect, baseline assessment for subsequent comparison if late hemodynamic compromise or tamponade is suspected after the patient has left the intensive care unit.

Absolute contraindications to the use of an ITA include previous damage from penetrating trauma or surgery and documentation of the artery as a major source of collateral perfusion to the mesenteric circulation in cases of chronic aortic thrombosis or to a lower extremity in patients with Leriche syndrome (unless lower extremity revascularization is performed concomitantly).^{84,85} Patients on chronic hemodialysis should have a free rather than an in situ ITA graft performed on the side of their arteriovenous fistula.⁸⁶ Severe obesity, chronic obstructive pulmonary disease (COPD), and diabetes may contraindicate the use of bilateral ITAs, but this is controversial and ultimately depends on individual preferences.⁸⁷ Although conventionally believed to be a relative contraindication to ITA use,⁸⁸ previous thoracic irradiation appears to confer no overt histologic changes relative to nonirradiated controls.⁸⁹ Long-term patency data, however, are scarce; therefore, use of ITA grafts in patients with previous mediastinal irradiation must be evaluated on a case-by-case basis.

Previous upper abdominal surgery or symptoms suggestive of mesenteric angina contraindicate the use of a gastroepiploic artery. Radial artery harvest is avoided in patients with Raynaud syndrome or on the same side in patients who have had recent radial arterial puncture at the time of preoperative coronary catheterization. We prefer to also avoid it, in a side-specific manner, in patients with carpal tunnel syndrome or with a history of previous penetrating trauma involving the wrist or forearm. It is important to both feel for an ulnar pulse and perform the Allen test, using a cutoff of 3 seconds, which has a 100% sensitivity for inadequate collateral hand circulation.⁹⁰ The former is important because, in rare cases, the ulnar artery may sometimes be congenitally absent with an otherwise normal Allen test.⁹¹

Asymptomatic carotid bruits have unreliable predictive accuracy,⁹² but their presence warrants carotid duplex examination if CABG can be performed on an elective basis.⁹³ Perioperative stroke risk is less than 2% in patients with carotid stenoses less than 50%, 10% when stenoses are 50% to 80%, and 11% to 19% in patients with stenoses of more than 80%.⁹⁴ A history of transient ischemic attack or stroke warrants a carotid duplex examination to rule out a carotid stenosis and an echocardiogram to rule out a cardiac embolic source or a patent foramen ovale. If no source is found and symptoms suggestive of vertebrobasilar insufficiency are elicited, MRI angiography of the arch vessels should be performed. Patients who had a recent stroke should ideally delay CABG for a minimum of 4 weeks to limit the risk of further neurologic damage. Combined CABG and carotid endarterectomy is controversial although data suggest that the development of postoperative stroke is related to surgical technique and patient factors rather than operative strategy.⁹⁵ Recent trends suggest that carotid artery angioplasty and stenting with concomitant CABG is emerging as an alternative to combined CABG and carotid endarterectomy.⁹⁶ Preoperative documentation of hemodynamically significant carotid stenoses allows for risk stratification, consideration of a staged procedure preceded by carotid endarterectomy, selection of special intraoperative monitoring, and optimization of blood pressure management perioperatively.

Medications

Aspirin and cardiac medications are continued up to the time of operation, with the exception of digoxin, which is discontinued one day prior to surgery. Warfarin is stopped several days (>5) before surgery in orally anticoagulated elective patients, who are started on low-molecular weight heparin when their international normalized ratio (INR) becomes 2.0 or less; emergent cases are reversed with fresh-frozen plasma, Octaplex, and intravenous vitamin K. Management of the ADP-dependent platelet inhibitors clopidogrel and ticagrelor⁹⁷ varies according to personal preferences; our preferred approach in stable patients is to stop the medication 1 week prior to operation with a minimum of 5 days.^{43,97} Furthermore, prasugrel is typically withheld for at least 7 days before elective CABG. With patients with drug-eluting stents that are within a year of insertion and who will not have their stented coronary segment(s) bypassed,

we prefer to keep them on clopidogrel right up to the day of operation. Patients who have been started on an ACE inhibitor prior to surgical referral should have postoperative serial serum creatinine assessments. If progressive elevation is noted (>25% of baseline), the ACE inhibitor should be stopped to allow the serum creatinine levels to normalize prior to operation.

Laboratory Tests

Complete blood counts, serum chemistries, liver function tests, coagulogram, electrocardiogram (ECG), chest x-ray, and urinalysis are routinely performed. Particular attention is given to a low platelet count (suggestive of possible heparin-induced thrombocytopenia in patients on heparin), an elevated serum creatinine (a strong predictor of increased operative mortality), and the presence of vascular calcification on the chest x-ray. Anterior Q waves with poor R wave progression on the ECG are indicative of transmural myocardial scarring and may warrant echocardiography or preoperative viability testing. Most patients will have undergone preoperative nuclear scintigrams and echocardiography. These are reviewed to determine the functional significance of borderline coronary stenoses and to provide an assessment of valve function, left ventricular systolic wall motion, diastolic function, and right ventricular contractility.

A major improvement in the preoperative evaluation in patients with poor left ventricular function and CHF has been the scintigraphic assessment of myocardial viability. Viability is best assessed with PET; recovery of regional and global left ventricular function after surgical revascularization is correlated with a higher preoperative blood flow and glucose uptake, indicative of less tissue fibrosis and a higher fraction of viable cardiomyocytes in the dysfunctional area (Fig. 88-2).⁹⁸ Results are best if both hibernating myocardium and angina symptoms are present and attributed to a myocardial territory subtended by a graftable vessel with significant proximal stenosis; conversely, patients with no viability, no angina symptoms, and diffuse CAD are less likely to derive a survival benefit compared with medical therapy after CABG. If PET is not available, dobutamine stress echocardiography or MRI may be used to identify reversible myocardial dysfunction; although not as sensitive as PET, dobutamine wall-motion indices are specific in predicting postoperative improvement.⁹⁹

Coronary Angiogram

Coronary angiography is still the fundamental diagnostic tool for describing the surgical anatomy of CAD. As a general rule, vessels 1.5 mm or larger with $\geq 50\%$ to 70% stenosis should be grafted. Consideration is given to smaller vessels if no other target is found in a coronary distribution where myocardial ischemia has been demonstrated on noninvasive testing. With modern techniques of CPB and myocardial protection, incomplete revascularization is rarely justifiable because of its known deleterious effects on short- and long-term outcomes.¹⁰⁰ Failure to bypass a functionally significant and stenosed coronary artery should therefore be exceptional and result from severe comorbidities, from nongraftability, from diffuse

FIGURE 88-2 ■ Myocardial viability assessment. This patient with congestive heart failure symptoms and inferior wall akinesis was evaluated prior to coronary artery bypass grafting (CABG) with ^{18}F -fluorodeoxyglucose (FDG) positron emission tomography and perfusion scintigraphy. Depressed ejection fraction (EF), viable myocytes (indicated by the normal FDG uptake), and the presence of a large posteroinferior perfusion defect were identified preoperatively. After CABG, the perfusion defect disappeared and the EF normalized. (Courtesy Robert S. Beanlands MD, Chief of Cardiology, University of Ottawa Heart Institute).

FIGURE 88-3 ■ Intramyocardial left anterior descending artery (LAD). The LAD goes downward (arrows) and, after several centimeters, upward on the angiogram (arrowheads). **A**, Right anterior oblique projection. **B**, Left anterior oblique projection.

aortic and branches calcification with inability to perform Y- or T-grafting, from conduit shortage, or from significant, unexpected intraoperative problems.

An intramyocardial LAD can be a vexing problem. Because LITA-LAD grafting provides a significant survival benefit in CABG patients,¹⁰¹ the failure to graft a stenosed LAD because of its intramyocardial location is clearly suboptimal. However, the situation can be identified preoperatively by seeing the vessel going downward and, after several centimeters, upward on the angiogram or by noticing that the LAD goes straight down to the apex without any curve (Fig. 88-3). Epicardial Doppler or retrograde probing of the LAD after performing a minute arteriotomy at its apical portion (or alternatively on a minor diagonal branch) can be used intraoperatively to identify the LAD at its proximal or mid portion.

Conduit Selection

Internal Thoracic Artery Grafts

The ITA is the preferred conduit for CABG and provides short- and long-term survival benefits in all patient subgroups, including those 75 years of age and older.¹⁰¹⁻¹⁰⁵

The steps in preparing the ITA conduit are described in Figure 88-4. Use of the LITA to graft the LAD (or a main target vessel on the left coronary circulation if the LAD is free of disease) should be performed except in rare circumstances such as preexisting or iatrogenic damage to the LITA, poor flow from severe spasm or dissection, significant ipsilateral subclavian stenosis, demonstrated involvement of the LITA in providing collateral supply to the lower extremity, mediastinal irradiation (if other arterial conduits are available), and emergency CABG with cardiogenic shock.

Bilateral ITAs should be used whenever possible, as this is associated with lower reoperation rates, lower late PCI rates, and possible long-term survival benefits.¹⁰⁶⁻¹¹⁰ Possible contraindications to the use of bilateral ITAs include emergency operation, insulin-dependent diabetes mellitus, obesity, and severe COPD for which the patient requires oral or intravenous glucocorticoid therapy. After decades of debate, use of bilateral ITAs appears not to increase the incidence of deep sternal wound infection except in emergent cases, in patients older than 70 years, and in patients with type I diabetes.^{109,111,112}

Skeletonization of an ITA involves dissection of the ITA without the accompanying periarterial venous and

FIGURE 88-4 ■ Preparation of the internal thoracic artery. **A**, After exposure of the posterior surface of the sternum and ribs, electrocautery is used to make an incision along the entire length of the sternum, medial to the internal thoracic artery (ITA). **B**, Cautious tension is applied posteriorly to expose the ITA branches, which are clipped and divided. Blunt dissection is used to mobilize the pedicle in areas with no branches. **C**, After all the branches are clipped, an incision is made lateral to the pedicle to free it from the chest wall along its entire length. **D**, After administration of heparin, the pedicle is divided and the distal end is ligated. Forceful blood flow should be expected from the proximal end. A vascular clamp is applied to the proximal pedicle to control blood flow. **E**, The distal end of the arterial conduit is dissected free from the surrounding venae comitantes and tissue, and **F**, the venae comitantes are clipped. (Adapted from Doty DB, Doty JR, editors: *Cardiac surgery operative technique*, ed 2, Philadelphia, 2012, Saunders, p 409, Figure 36-6.)

fascial tissue. Given that the ITA is a delicate structure, meticulous attention must be paid to avoid artery damage, dissection, or both. Data support the notion that skeletonized ITA use does not impact long-term survival or graft patency, while decreasing sternal wound complications.^{109,113-118} The benefits in vascularity are correlated with decreased sensory deficits to the precordium.¹¹⁹ Patients older than 75 years also appear to benefit from the sternal vascularity benefits of skeletonized ITA use.¹⁰² Excellent results have been reported with the use of skeletonized bilateral ITAs in diabetic patients, and yet some studies showed obese diabetic women had an increased incidence of deep sternal wound infection.^{120,121} Other studies, however, found no association between skeletonized bilateral ITA harvesting in diabetic patients and sternal wound infection.¹²²

Whether a free or pedicled ITA graft is performed makes little difference with respect to patency and endothelial function, provided that a flawless anastomotic technique is used.^{123,124} It is more important to avoid short conduit length, which may invariably lead to angle distortion and resultant compromise in flow and patency. A pedicled ITA graft that appears too short is better cut proximally and repositioned onto the aorta or onto another ITA than left under tension.

In some patients, ITA flow may be very low (i.e., less than 20 mL/min) prior to construction of the anastomosis. This may be because of spasm, small size, or intraoperative injury such as an intimal dissection. If an area of injury is suspected, the ITA should be either converted to a free graft (if long enough) or transected a few millimeters above and below the injury site, the two stumps beveled, and an end-to-end anastomosis performed with 8-0 polypropylene. If no injury is apparent, the ITA in most cases may still be used for grafting, as this does not appear to result in an increased incidence of angiographic string sign or graft occlusion at 1 year postoperatively.¹²⁵ Unrecognized ITA intimal dissections in some cases may spontaneously heal with anticoagulation, antiplatelet therapy, and vasodilators alone.¹²⁶

Radial Artery Grafts

Controversy exists regarding the benefit of the radial artery as an alternative to the saphenous vein. More than five randomized controlled trials to date have compared the use of the radial artery with the saphenous vein as a conduit for CABG.¹²⁷⁻¹³⁴ At 1 year, the radial artery has been found to be equivalent to the saphenous vein in terms of angiographically determined patency.^{127,131,132} At 5 years, however, the radial artery appears to offer either slightly superior or similar patency rates compared with saphenous vein grafts.^{130,132,135} In patients older than 70 years at the time of operation, the use of the radial artery was associated with improved survival at 6 years.¹²⁸ Predictors of lower radial artery graft patency rates when compared with vein grafts include female patients and patients with peripheral vascular disease.¹³⁶ Although radial grafts are highly versatile and can be used for virtually any type of grafting configuration (e.g., aortocoronary, Y, or T), they should not be used to graft coronaries with less than 70% stenosis because of reduced patency and vulnerability for competitive flow physiology.^{137,138}

Intraoperatively, the radial artery may be treated immediately following harvest with a blood/phenoxybenzamine flush (100 mg of phenoxybenzamine mixed in 50 mL of heparinized blood) and left soaking in this mixture for 5 to 30 minutes. Phenoxybenzamine, a non-competitive α_1 -antagonist agent, is nontoxic for endothelial cells and highly effective in preventing acute spasm of the radial artery.^{139,140} In one larger study, phenoxybenzamine was shown to reduce the incidence of perioperative myocardial injury and adverse cardiac events.¹⁴¹ Alternatively, nitroglycerin can be used to dilate the radial artery prior to grafting. The steps in preparing the radial artery conduit are described in Figure 88-5.

Radial artery harvest is contraindicated in the presence of insufficient collateral supply to the hand or Raynaud

FIGURE 88-5 ■ Open radial artery harvest. **A**, An incision is made in the forearm following the brachioradialis muscle belly. As the dissection is carried deeper, the lateral antebrachial cutaneous nerve will lie lateral to the dissection plane along with the brachioradialis muscle. **B**, The deep fascia of the forearm is opened, exposing the radial artery and veins. The superficial radial nerve also lies lateral to the dissection. **C**, The radial artery and veins are mobilized by clipping branches and using blunt dissection of nonvascular tissue. A vessel loop is used to retract the conduit, avoiding excessive manipulation of the radial artery, which may induce spasm. The dissection is carried out proximally to the recurrent radial artery branch and distally to the fascia enclosing the tendons of the wrist. (Adapted from Doty DB, Doty JR, editors: *Cardiac surgery operative technique*, ed 2, Philadelphia, 2012, Saunders, p 417, Figure 36-9.)

syndrome, in patients with high manual demands such as professional musicians, in the very elderly (who have a high prevalence of radial arteriosclerosis and are unlikely to derive a survival benefit from its preferential use over a vein graft), during emergency operations, and in patients who are likely to require postoperative vasopressors, such as those with very poor left ventricular function. Radial artery use should be expressly discussed during informed patient consent, as the incidence of neurologic complications is approximately 30% and most often consists of decreased thumb strength and sensation abnormality.¹⁴² Diabetes, peripheral vascular disease, elevated creatinine levels, and smoking are associated with an increased incidence of these complications, which resolve with time in most patients.¹⁴³

In efforts to minimize radial artery graft spasm, the predominant cause of early graft failure, the radial artery can be harvested with surrounding perivascular tissues, thereby using an atraumatic “no-touch” technique. Next, replacing mechanical dilation of the free radial artery, pharmacologic dilation with papaverine (or phenoxybenzamine) may enhance nitric oxide production, resulting in decreased endothelial dysfunction. Finally, postoperative radial artery spasm prevention can be considered with either calcium channel blockers or nitrates.¹⁴⁴ Despite little evidence-based literature advocating

calcium channel blocker therapy for the prevention of radial artery graft vasospasm, more than 90% of Canadian surgical centers report routine use of calcium channel blocker prophylaxis lasting from several weeks to 6 months.^{15,145-147}

Endoscopic radial artery harvest gained popularity in the past decade because it provides better cosmesis and less pain compared with open harvesting.¹⁴⁸ Unlike the concern with regard to patency reported in endoscopic vein harvesting, mid-term patency using endoscopic radial artery harvesting seems equivalent to open harvesting.¹⁴⁹

Gastroepiploic Artery Grafts

The gastroepiploic artery is a conduit with a higher propensity for intraoperative problems and a lower postoperative patency than the radial artery. Excellent results have been reported by several groups who have developed an expertise with its routine use with 4- to 5-year patency rates of 86% to 90%.^{87,150-152} To date, there has been one randomized controlled trial comparing the use of the gastroepiploic artery with use of the saphenous vein graft.¹⁵³⁻¹⁵⁵ At 6-month angiographic follow-up, there appeared to be no differences in patency between conduits,¹⁵³ although it appeared the patency of the gastroepiploic artery was more influenced by competitive coronary flow.¹⁵⁴ Despite these encouraging results, several factors make it a difficult conduit to systematically recommend: harvest elicits spasm, kinking and torsion may go unrecognized, and anastomotic problems are more likely the result of the small size of the vessel. One study has suggested that use of the gastroepiploic artery to graft coronaries with only moderate proximal stenosis (70% to 80%) or with poor runoff should be avoided, because this results in decreased patency,¹⁵⁶ whereas another study has suggested that its use as a free graft is also associated with a lower patency than the in situ configuration.¹⁵⁷ Based on this evidence, alternative arterial conduits, or possibly saphenous vein conduits, should be exhausted before considering use of the gastroepiploic artery as the conduit of choice for primary revascularization. Moreover, a recent review emphasized that compared with vein graft patency rates, gastroepiploic artery patency rates were inferior during right coronary artery grafting.¹⁵⁸

Saphenous Vein Grafts

Because of their lower short- and long-term patency compared with ITAs, saphenous veins have not been the conduit of choice for CABG for approximately 20 years.¹⁰¹ Nevertheless, saphenous veins are the most often used and remain useful in several situations. They constitute the most readily available CABG conduit, provide immediate and reliable coronary flow with a low propensity for spasm or severe compromise during low-output states, and constitute a time-honored means of coronary revascularization during emergency procedures or in patients with severe comorbidity and limited life expectancy in whom procedural simplicity, expeditiousness, and reliability are most desirable. Furthermore, current-era

FIGURE 88-6 ■ Interrupted skin incisions to harvest the greater saphenous vein. Compared with a long leg incision, skip incisions provide more cosmesis and lower infection rates while allowing for a direct-vision harvest of the vein. (From Sellke F, Ruel M, editors: *Atlas of cardiac surgical techniques*, Philadelphia, 2009, Saunders.)

antiplatelet and cholesterol medical therapy may improve saphenous vein graft patency beyond that reported in initial CABG series.^{28,159,160} Several groups have demonstrated saphenous vein graft patency rates surpassing radial artery patency rates especially when conduits are grafted to moderately diseased arteries¹⁶¹⁻¹⁶³; furthermore, a recent meta-analysis demonstrated higher side-to-side sequential vein graft patency compared with single vein grafts.¹⁶⁴

A variety of minimally invasive techniques are widely available for retrieval of the saphenous vein. The spectrum of techniques range from skip incisions (Fig. 88-6) to the use of commercially available endoscopic systems.^{165,166} These techniques have been shown to improve patient quality of life and lower harvest site infections.^{167,168} On the opposite end of the spectrum, some centers have advocated the use of pedicled saphenous veins to improve on conduit patency and reduce venospasm.¹⁶⁹ Results from three small randomized controlled trials comparing the no-touch saphenous vein harvesting to conventional harvesting demonstrated superior patency rates at mid-term (18 months) and long-term (8.5 years) follow-up along with improved endothelial integrity.¹⁶⁹⁻¹⁷² With more centers performing this technique, further investigation is needed to elucidate the best method for vein harvesting.

Similar to the radial artery, endoscopic vein harvesting was met with enthusiasm a decade ago as studies showed improved cosmesis and lower infection rates compared with open harvesting.^{173,174} However, excitement was tempered by a large study reporting lower patency rates and higher rates of death, MI, or repeat revascularization at 3 years compared with open harvesting.¹⁷⁵

Other Conduits

The lesser saphenous vein, inferior epigastric artery, and right gastroepiploic artery are three alternative autologous conduits. They are rarely needed for primary revascularization, but they may be useful in patients lacking conduit options. Finally, in rare circumstances, cadaveric cryopreserved saphenous veins, bovine

chemically treated ITAs, or expanded polytetrafluoroethylene grafts can be used.

Operative Preparation

Intraoperative preparation by the anesthesiologist includes upper extremity peripheral intravenous and arterial access (contralateral to the side of radial artery harvest), induction of general anesthesia, endotracheal intubation, central venous access, and occasionally placement of a pulmonary artery catheter. Intravenous antibiotics with gram-positive coverage are administered 30 to 60 minutes prior to the skin incision. Perioperative antibiotic regimens vary on institutional practices, but often include cefuroxime (1.5 g intravenously [IV] every 12 hours) or cefazolin (1 to 2 g IV every 8 hours for 48 hours); in patients with penicillin allergy, vancomycin (1 g IV every 12 hours) is continued for at least two doses until lines and tubes are removed.¹⁷⁶ A nasogastric tube and transesophageal echocardiography probe, if available, are advanced in the esophagus. Baseline measurements of filling pressures, cardiac output, valvular and ventricular function, arterial blood gases, activated clotting time, hematocrit level, and electrolyte levels are obtained prior to the surgical incision.

The patient is prepared and draped, and a limited midline skin incision is made from the manubrium of the sternum to the xiphoid process. If use of a gastroepiploic artery is planned, the median sternotomy skin incision is carried 2 to 3 inches below the xiphoid. Median sternotomy is performed through this incision by slightly mobilizing the subcutaneous fat in the upper portion of the wound away from the pectoralis muscle while an assistant retracts it superiorly and by proceeding from bottom to top of the sternum with the saw. The assistant then starts harvesting the radial artery, saphenous vein, or both. Meticulous hemostasis is ensured at all stages (unless the patient is acutely ischemic or hemodynamically unstable), because this prevents continuous oozing during the remainder of the operation, minimizes the use of the cardiotomy suction with its potential detrimental effects, prevents coagulopathy, and effectively saves time before closure. Our preference is to open the pericardium before harvesting the ITAs, because this does not lengthen the procedure. In addition, this allows not only digital assessment of the aorta and the performance of epiaortic scanning early in the operation (with the planning of alternate cannulation sites and no-touch Y arterial grafting if significant aortic disease is unveiled), but also the identification of target vessels, the estimation of needed conduit length, and the expeditious cannulation if sudden hemodynamic collapse occurs. Epiaortic scanning is useful as a routine adjunct and can detect ascending aortic atherosclerosis in up to 30% of patients undergoing isolated CABG.¹⁷⁷ Contemporary guidelines recommend intraoperative transesophageal or epiaortic scanning of the aorta to detect nonpalpable plaque (class I, evidence B) and reduce the cerebral embolic load (class IIa, evidence B) in patients at high risk of experiencing a perioperative neurologic event.¹⁷⁸ If epiaortic scanning is unavailable, the incidence of perioperative CVA after CABG can still be minimized by routine preoperative

carotid screening, intraoperative transesophageal echocardiography, and a tailored approach to revascularization, thereby avoiding manipulation of the diseased aorta. This includes the use of alternate cannulation sites, fibrillatory arrest, and off-pump revascularization techniques; in a series of more than 6000 CABG patients in whom this approach was used, Trick and coworkers reported a stroke incidence of less than 1%, even in high-risk patients.¹⁷⁹

The ITAs are harvested and are transected distally only after systemic administration of heparin. There are two ways to perform this while minimizing bleeding during harvest of the second ITA: either a partial dose of heparin (e.g., 5000 to 10,000 units) is given at the completion and prior to transaction of the first ITA (with a completion dose administered prior to transaction of the second ITA), or both ITAs are transected at the same time after the second ITA has been harvested and the full dose of heparin given.

Cardiopulmonary Bypass and Cardioplegia

CPB is established with ascending aortic cannulation, right atrial venous cannula drainage, mild hypothermia (32° to 34° C), and alpha-stat pH management. Venting is performed via the proximal ascending aorta by using the antegrade cardioplegia delivery catheter, often at a site to be used later for a proximal anastomosis. Antegrade intermittent cold blood cardioplegia provides adequate myocardial protection for most primary revascularization cases; consideration is given to a combination of antegrade and retrograde routes in severely ischemic patients or when the LAD is obstructed or severely stenotic.¹⁸⁰ Topical cooling makes little difference on myocardial temperature and outcome when combined with antegrade cold blood cardioplegia and has been associated with an increased incidence of postoperative hemidiaphragmatic paresis and pleural effusions.¹⁸¹

Intraoperative transcranial Doppler scanning of the middle cerebral arteries, if available, constitutes a useful adjunct during CPB cases. In our experience, it has helped design minor but effective modifications in cannulation, perfusion, clamping, and venting techniques that have minimized the frequency and overall number of high-intensity transient signals.¹⁸² Use of the cardiomy suction is best avoided because of its potentiation of clotting activation, micelle formation, and microembolism during perfusion. It can be replaced by a cell-saver device during routine cases. Moderate hypothermia and slow rewarming as well as meticulous control of blood glucose levels can also help decrease the incidence of postoperative neurocognitive deficits.^{183,184}

Special Situations

Diffuse Aortic Disease. One of the most formidable technical obstacles that can be encountered during CABG is diffuse disease of the aorta and its branches. Manipulation of a diseased aortic segment may lead to embolization and constitutes the most important risk factor for stroke after CABG.¹⁸⁵ If the aortic disease is focal and does not involve the distal third of the ascending aorta,

the area can usually be avoided during cannulation, clamping, and construction of proximal anastomoses (under single cross-clamping). Multifocal disease, diffuse disease, or disease involving the distal third of the ascending aorta, however, mandates the use of femoral or axillary artery cannulation; the relocation of proximal anastomoses to the proximal ascending aorta, brachiocephalic artery, or descending aorta; the use of hypothermic fibrillation or hypothermic circulatory arrest; and, in some cases, ascending aortic replacement. Fortunately, widespread familiarity with off-pump and Y-grafting techniques has significantly increased the options for managing patients with diffuse aortic disease. In most cases of diffuse aortic disease, an off-pump aortic no-touch CABG operation with bilateral pedicled ITAs or Y or T arterial graft configuration can be performed with acceptably low risk, provided the patient is hemodynamically stable and not acutely ischemic.¹⁸⁶ If refractory hemodynamic instability develops, the patient must be managed with cannulation of the axillary or femoral artery,¹⁸⁷ establishment of CPB, hypothermic fibrillatory arrest during performance of distal anastomoses, and construction of the proximal anastomoses to the innominate artery or to a disease-free area of the ascending aorta using a special, local-control device¹⁸⁸ or during a short period of hypothermic circulatory arrest.⁸³

Preoperative Cardiogenic Shock. Preoperative cardiogenic shock requires immediate establishment of CPB, performed either via femoral cannulation or sternotomy depending on patient characteristics (such as redo operation or a history of previous aortobifemoral grafting) and the surgeon's preferences. If time and hemodynamic status allow, patients should have an intra-aortic balloon counterpulsation pump inserted preoperatively or stabilized with a nondurable percutaneous mechanical circulatory support device such as the Impella 2.5 or 5.0 (Abiomed, Danvers, MA).^{189,190} Combined antegrade and retrograde cardioplegia delivery with warm induction and warm reperfusion techniques can have a net benefit in those patients. Although consideration is given to the use of one ITA graft if the patient is hemodynamically stable, the use of an all-saphenous vein operation is appropriate because of high immediate myocardial demands and anticipated need for postoperative inotropes.¹⁹¹ Revascularization involves the performance of at least one graft to each ischemic myocardial territory.

Medication-Related Coagulation Impairment. Whether the use of antifibrinolytics is mandated in routine CABG cases remains controversial. Recently, the serine protease inhibitor aprotinin has come under scrutiny. Previous reports had suggested that aprotinin may adversely impact renal, myocardial, cerebral, and pulmonary function.¹⁹²⁻¹⁹⁵ In an observational trial involving 3876 patients, Mangano and colleagues found that aprotinin use was associated with an increase in overall mortality at 5 years.¹⁹² Following publication of this study, use of aprotinin dropped precipitously, although some studies have suggested that patients undergoing off-pump CABG may in fact benefit from aprotinin use.^{196,197}

Advances in antiplatelet therapy have revolutionized the management of patients with CAD; however, the antiplatelet effects can also impact postoperative hemostasis.¹⁹⁸ Transfusions of platelets, fresh-frozen plasma, and cryoprecipitate may therefore be needed in these patients. Patients on abciximab may benefit from the routine administration of a single platelet transfusion after protamine administration; this approach appears to decrease the rate of reexploration for bleeding.¹⁹⁹

Previous Tracheostomy. The presence of a tracheal stoma in patients with previous total laryngectomy who require cardiac operations is associated with an increased risk of wound complications, mediastinitis, tracheal injury, or stoma necrosis when a full sternotomy is used. In these patients, a manubrium-sparing sternotomy can be used, where the upper edge of the sternotomy does not extend beyond the top of the third rib. Slow progressive opening of the retractor allows for the operation to be conducted successfully while minimizing the possibility of manubrial fracture, bleeding, and patient discomfort. An alternative approach is to incise the sternum transversely at the second intercostal space and complete the median sternotomy longitudinally down to the xiphoid process.²⁰⁰

Distal Anastomoses

Construction of distal coronary anastomoses begins once the first dose of cardioplegia has been delivered. With current methods of myocardial protection and considering the increased prevalence of diffuse CAD in CABG patients, there is little justification for performing proximal anastomoses first during on-pump CABG. Proximal anastomoses are constructed either sequentially (each distal followed by its proximal under single cross-clamping) or all at once after completion of distal anastomoses. One exception to this approach is during performance of arterial Y- or T-grafting, because the surgeon may complete all proximal conduit anastomoses onto one to two pedicled ITAs prior to the establishment of CPB; this strategy minimizes unnecessary CPB time and allows for the assessment of free flow in each ramus of the configuration prior to distal grafting.

Although the order of revascularization is not of critical importance during on-pump CABG, the first graft performed is usually that to the inferior circulation, followed by the lateral wall, the diagonal system, and the LAD artery. Vessels that are completely occluded and for which a free graft is planned may benefit from construction of the distal anastomosis early in the revascularization sequence to improve cardioplegic delivery to the subtended myocardium.

Many conduit-graft configurations are possible, and the choice is based on the needs of the patient. The pedicled LITA is usually grafted to the LAD, although the pedicled right internal thoracic artery (RITA) can also be used with success and placed in the superior mediastinum to decrease the risk of injury during subsequent sternotomy. The next preferred conduit (i.e., the second ITA, followed by the radial, gastroepiploic artery, and saphenous vein) is kept for the target vessel in decreasing

order of anatomic importance. Poor-quality, diffusely diseased coronary arteries do not necessarily only deserve a vein graft, as the short- and long-term patency of an ITA or radial graft to a diffusely stenotic vessel may be considerably better. Conduit length problems resulting in inappropriate anastomotic tension are almost always solvable by the use of arterial Y-grafts, which are avoided with saphenous veins because differences in conduit size can result in unpredictable flow patterns.

Exposure of the main coronary branches is not problematic during on-pump CABG. The inferior wall may be exposed by packing a small sponge against the inferior vena cava at the right inferior aspect of the oblique sinus. The lateral wall may be exposed by gently twisting and folding the heart on itself in the long axis and placing a sponge underneath to expose the marginal branches. The anterior wall is exposed by a single sponge under the left ventricle.

The most proximal disease-free portion of the coronary artery to be grafted (i.e., immediately after the most distal involvement) is selected for the anastomosis. The epicardium is incised over the area of the coronary artery with a no. 15 blade or a special rounded blade. The anterior surface of the artery is cleared by gentle transverse brushing with the scalpel. Even with cardioplegia, careful inspection of the artery will reveal a thin central line that is red or translucent, indicating the lumen. The anterior wall of the artery is opened longitudinally over this line by caressing gently with the scalpel so as to not damage the posterior wall. Administration of a small amount of cardioplegia to distend the coronary artery lumen may be useful during this step, especially for small (≤ 1 mm) vessels. Occasionally, when the anterior wall of the artery cannot be placed under proper tension, it may be opened by stabbing it with a sharp-pointed scalpel. The blade must enter the artery obliquely and superficially, so as to not penetrate the posterior wall. The incision is enlarged with angled scissors to a length of 4 to 6 mm for end-to-side anastomoses, and 3 to 5 mm for side-to-side anastomoses. The epicardial incision is extended beyond each angle of the arteriotomy to facilitate the anastomosis. The artery may be sized and proximal, and distal patency can be assessed by passing measuring probes into it. Aortic root venting is used only as necessary so as to not introduce an excessive amount of air into the ascending aorta. The distal end of the conduit is incised longitudinally for approximately 20% longer than the coronary arteriotomy; this in conjunction with slightly further spacing of suture bites on the conduit than on the coronary enables the desirable "cobra head" appearance (Fig. 88-7).

Many anastomotic techniques exist, each with advantages and disadvantages. For the sake of reliability under all circumstances, each surgeon should probably limit himself or herself to one main anastomotic technique that is perfectly mastered and can be used with all conduit types, for end-to-side as well as side-to-side anastomoses, and during on-pump as well as off-pump CABG. General principles include the use of 7-0 or 8-0 polypropylene, the use of a no-touch technique in which the intima of the coronary and the conduit are never grabbed, and compulsive attention to the geometric distribution of sutures as the anastomosis is performed, because an

FIGURE 88-7 ■ End-to-side distal anastomosis. After incising the epicardium over the selected coronary artery using a no. 15 blade, an arteriotomy is performed to match the end of the graft. The graft is anastomosed onto the coronary artery using a running 7-0 polypropylene suture. Constant attention is given to the overall anastomosis geometry. (From Sellke F, Ruel M, editors: *Atlas of cardiac surgical techniques*, Philadelphia, 2009, Saunders.)

otherwise adequate but deformed anastomosis may be nonfunctional or prone to thrombosis. Another principle we enforce is that no impediment to native coronary flow should result from construction of an anastomosis, therefore mandating flawless patency at both anastomotic angles so that if for some reason the conduit becomes nonfunctional, native coronary flow will at least be the same as if a bypass graft had not been performed onto this coronary artery.

We prefer to use sequential grafts within a single coronary distribution only (e.g., for two marginal branches of the circumflex system), to avoid possible flow diversion from one myocardial territory to another. Other groups have reported good results using a T-graft configuration that may bridge two or even three myocardial territories.^{186,201} In general, sequential grafts allow for a greater number of arterial anastomoses and, with vein grafts, contribute to an increased long-term patency.^{163,201} Transverse sequential side-to-side anastomoses may be used for saphenous vein grafts with excellent patency rates¹⁶⁴ but are relatively contraindicated with arterial grafts. Perfect orientation of the sequential arterial anastomoses with respect to each other and avoidance of tension or excessive redundancy on the conduit are crucial. Because of the potential to jeopardize revascularization of two or more vessels, any sequential graft that might appear technically unsatisfactory is best redone or replaced with individual grafts.

Coronary Endarterectomy

Coronary endarterectomy is a technique that preceded the invention of CABG.⁵ It is now reserved for select

A

B

FIGURE 88-8 ■ Coronary endarterectomy. **A**, Representative illustration of a large atheroma removed from the left anterior descending artery. **B**, Specimen removed from a completely occluded right coronary artery and subsequently bypassed with a saphenous vein graft. (Courtesy Dr. John Veinot, Department of Pathology, Ottawa Hospital, Ottawa, Ontario, Canada.)

cases of severe diffuse disease where no anastomotic site can be found on a coronary artery that supplies an ischemic and viable myocardial territory (Fig. 88-8). This procedure should not be used because of technical failure to find the true lumen, such as occurs when a diffusely diseased vessel is mistakenly opened into a lateral plaque. Arteries that can be seen on coronary angiography do have a lumen, which can be found despite poor target site selection or extraluminal opening by carefully extending the arteriotomy proximally and distally into the true lumen and performing a long patch angioplasty by using the conduit as an onlay patch. Endarterectomy should also only be used on vessels with high-grade stenoses (>80%). Endarterectomy is combined with an onlay patch angioplasty of the endarterectomized vessel, and a bypass graft is performed using the same conduit. When reserved for carefully selected situations, coronary endarterectomy has been associated with a rate of

perioperative MI of 5% or less, a graft–coronary axis patency of 72% at 30 months, and a good functional outcome that can approach outcomes seen in non-endarterectomized patients.²⁰²⁻²⁰⁴

Sutureless Distal Coronary Connectors

Significant advances have been made with automated coronary connectors and self-closing U-clip distal anastomotic devices. Preliminary reports on the use of these devices in humans describe geometrically adequate anastomoses, excellent immediate graft flows, and good patency at 3- and 6-month angiographic follow-up.²⁰⁵⁻²⁰⁷

Proximal Anastomoses

Most proximal anastomoses are made on the ascending aorta, but alternative sites such as the brachiocephalic artery, axillary artery, and descending aorta can be used in special situations. Y- and T-grafting involves constructing the inflow anastomosis of a free arterial graft to an in situ arterial conduit, using either an end-to-side or a side-to-side configuration. General principles of proximal anastomosis construction include insurance of a perfect graft lie (i.e., without torsion, tension, or excessive redundancy) and the minimization of aortic manipulations.

Although preferences vary, the use of a side-biting tangential clamp is best avoided because of its association with increased cerebral microembolic load and S-100 release during CABG.²⁰⁸ In our experience, several techniques can be used to reduce this embolic load to levels equal or below that of single aortic cross-clamp proximal techniques. These consist of (1) using a tangential side-biting clamp only in the presence of a nondiseased ascending aorta (Fig. 88-9), (2) releasing the cross-clamp and applying the side clamp while the pump is momentarily stopped, (3) irrigating the inside of the aorta after punch holes are made, (4) completely displacing air prior to tying the last proximal anastomosis either by saline instillation or by removal of the bulldog clamp on one of the anastomosed free arterial grafts, which backfills the aorta with blood, and (5) releasing the clamp while the pump is momentarily stopped.

To perform a proximal anastomosis a longitudinal slit, approximately 3 mm in length, is made with a no. 11 blade at the chosen site(s) in the aorta. A punch of either 4.0 (for free arterial grafts) or 4.5 mm (for saphenous vein grafts) in diameter is slipped completely and freely into the aorta through each slit and closed so as to punch out a circular piece of aorta at each site (see Fig. 88-9). Each conduit is irrigated intraluminally and its orientation determined under direct vision, measured so as to not prove too short or redundant once the heart fills (pinching of the venous line to fill the right heart is useful in evaluating this), occluded with a light bulldog clamp, spatulated at its proximal end to a perimeter approximately 20% longer than the aortic punch hole, and connected to the aorta using 6-0 polypropylene. If an arterial conduit appears too short, either it is anastomosed in an end-to-end fashion onto a short segment of saphenous vein, which is itself anastomosed to the aorta, or the

FIGURE 88-9 ■ Proximal anastomosis using a side-biting clamp. With the use of a side-biting clamp and after a small (4- to 4.5-mm) aortotomy is performed, the proximal anastomosis is accomplished with a running 6-0 polypropylene suture. (From Sellke F, Ruel M, editors: *Atlas of cardiac surgical techniques*, Philadelphia, 2009, Saunders.)

arterial graft is anastomosed side-to-side (as a Y-graft) onto another arterial graft.

Sutureless Proximal Coronary Connectors

Commercially available automated proximal aortic connectors have been used successfully by a growing number of groups with good patency rates; however, a prospective randomized controlled trial is needed to explore some concerns regarding early graft closure.²⁰⁹⁻²¹³ Advantages of these connectors include the avoidance of aortic manipulations (except at the anastomotic site) and ease of use, especially for off-pump or robotic-assisted procedures.

Intraoperative Graft Assessment

The high prevalence of small and diffusely diseased target vessels in CABG patients and the increasingly challenging surgical techniques used (such as complex arterial grafting and off-pump procedures) may justify routine graft validation in the operating room. One practice, although subjective, is to gently probe each anastomosis at critical points during construction to ensure proximal, distal, and conduit patency, and rule out a purse-string effect that may insidiously occur if too large or too few bites are taken around the anastomosis, if its geometric configuration is imperfect, or if the assistant pulls excessively on the suture when “following.”

The most widely used modality of objective graft assessment is transit-time flow measurement (TTFM). With this tool, a diastolic-to-systolic perfusion pattern of at least 2 : 1 for grafts constructed to vessels overlying the left ventricle (such as the LAD and circumflex branches)

and a pulsatility index less than 3 are a good predictor of patency, whereas low absolute flow values can be the result of arterial spasm without anastomotic error.^{214,215} Unfortunately, specific cut-off recommendations for graft revision have not been clarified and TTFFM remains imperfect in detecting less than critical stenosis on the graft or at the anastomosis, regardless of the adjunctive use of spectral or fast Fourier transformation analysis.²¹⁶ Other modalities such as high-frequency epicardial echocardiography and power Doppler imaging have been described, but experience is still limited.²¹⁷ Thermal imaging has limited image resolution and is largely unsuitable for off-pump or minimally invasive surgery.²¹⁸

Intraoperative fluorescent cardiac imaging is clinically safe and may prove clinically useful.²¹⁹ This modality uses a 0.5-mL injection of indocyanine green and a portable imaging device to visualize coronary anatomy and grafts during conventional CABG, off-pump coronary artery bypass (OPCAB), or minimally invasive direct coronary artery bypass (MIDCAB). Graft and coronary visualization is very good, but anastomotic resolution needs improvement and overlying fat or muscle can artificially obscure the penetration and detection of indocyanine green (ICG) fluorescence. The modality works best with skeletonized arterial grafts and saphenous vein grafts.

Routine intraoperative completion angiography in the setting of a hybrid operating room has shown, in one study, that up to 12% of bypass grafts may have important angiographic defects that need to be addressed intraoperatively.²²⁰ Further studies are needed to clarify the role of completion angiography in hybrid revascularization.

Weaning from Cardiopulmonary Bypass

Once the proximal anastomoses are completed, each vein graft is de-aired with a 27-gauge needle prior to release of the bulldog clamp. Graft conduits are examined for adequateness of lie and hemostasis at each anastomotic site and side branch while the mean arterial pressure is increased to at least 70 mm of Hg. Distal anastomotic jet bleeding is repaired with a single stitch of 7-0 Prolene; if the toe or heel is involved, repair may compromise the anastomosis, and consideration is given to preparing cardioplegia and reapplying the cross-clamp to redo the anastomosis. It is preferable to spend 10 to 15 extra minutes in redoing an anastomosis that has a significant leak at or near the angle than repairing it with a potential for distortion or occlusion. The epicardium may be used to cover and repair small lateral anastomotic leaks but should not be used near an anastomotic angle.

Preparation of the patient for weaning from CPB involves a routine but thorough assessment of the cardiac, pulmonary, and metabolic systems. The chosen temperature for weaning, a point of current controversy, is reached by slowly rewarming the patient and avoiding hyperthermia.^{183,221} Hematocrit level and metabolic and electrolyte balance are checked and corrected as necessary. The trachea is suctioned and the lungs are reexpanded by hand under direct vision and mechanically ventilated with 100% O₂. Respiratory monitors and alarms are reactivated. The pleural spaces are checked for the presence of fluid or pneumothorax. Atrial and

ventricular epicardial pacing wires are affixed onto the heart and exteriorized on the chest, and heart rhythm and rate are optimized by using synchronized cardioversion or pacing as necessary. Sinus rhythm or atrial pacing at 75 to 95 beats per minute is ideal for weaning, although patients with significant diastolic dysfunction from left ventricular hypertrophy or with incomplete revascularization may benefit from a slower atrial rate in conjunction with a slightly prolonged atrioventricular interval. The ECG is examined for ST-segment changes suggestive of ischemia; if ischemia is present, reassessment and reconstruction of a graft must be considered.

The perfusionist progressively clamps the venous line to provide preload to the ejecting right ventricle, which in turn results in left ventricular preload. Afterload is managed by the anesthesiologist by using either an alpha-agonist agent such as phenylephrine or, in some cases, a direct vasodilator such as nitroprusside. Contractility is assessed by observing left and right ventricular contraction and the evolution of pulmonary arterial pressures during the weaning process, which are reflective of ventricular function, except in cases of pulmonary vascular hypertension. Several adjuncts may be used when weaning is difficult. First, each of the previously described steps is rechecked and corrected as necessary while CPB support is reestablished and a period of reperfusion on the empty beating heart is reinitiated. Second, consideration is given to ischemia or intracoronary air while grafts are reassessed. Third, inotropic support and intra-aortic balloon pump (IABP) are used as necessary. Inotropic and IABP use in nonemergency patients with good left ventricular function preoperatively is abnormal and warrants questioning the adequacy of revascularization (i.e., nonfunctional grafts, plaque or cholesterol embolism during the construction of anastomoses, grafting of wrong coronary vessels or even a coronary vein), and justifies a low threshold for redoing or adding one or several grafts. Further attempts at weaning from CPB are taken after reconsidering the previously mentioned points. If weaning is still unsuccessful after many attempts and clearly related to poor contractility, consideration is given to the use of extracorporeal membrane oxygenation or mechanical ventricular support as a bridge to recovery.

Once the patient is satisfactorily weaned from CPB, the venous cannula is removed and the atrial purse-string suture snared but not tied. The venous line is then sumped with normal saline to return blood to the heart-lung machine reservoir. The aortic line is checked for air that may have migrated from the left ventricle during cardiac ejection, and the perfusionist transfuses aliquots of remaining pump blood according to the directives of the surgeon and anesthesiologist. Excessive right ventricular distention and pulmonary diastolic venous hypertension of more than 22 to 25 mm of Hg are avoided. If these develop and mean arterial pressure is satisfactory, IV nitroglycerine is used as a preload reducer and pulmonary venodilator.

Protamine is administered once stable hemodynamics is achieved and when reestablishment of CPB for support or technical reasons is unlikely to be needed. Chest tubes are inserted in the posterior pericardium, in the anterior

mediastinum, and into each pleural cavity entered. Care is taken at ensuring that chest tubes do not lie in proximity to a graft once the chest is closed: not only could they mechanically compress the graft and lead to distortion and thrombosis, but they may also result in damage if the graft is entrapped into a side-hole of the tube during suction.

After administration of the first dose of protamine, the aortic cannula is removed from the ascending aorta in case of hemodynamic collapse caused by an adverse protamine reaction. Cannulation purse-string sutures are securely tied and reinforced with pledgeted stitches as needed. Hemostasis is checked at each anastomotic site, along each conduit, at all cannulation sites, and on the chest wall. If, despite these measures, blood accumulation is still noted in the pericardium, the left atrial appendage is examined for possible damage caused by the cardiotomy suction during CPB. Radio-opaque markers are left around proximal vein graft anastomoses. The pericardium is partially reapproximated over the anterior left ventricle but not closed to avoid adverse hemodynamic effects. Routine closure of the sternotomy incision concludes the operation.

SPECIAL FEATURES OF POSTOPERATIVE CARE

Early Postoperative Period

Despite unclear evidence, patients with a radial, gastroepiploic, or inferior epigastric artery graft are started on intravenous nitroglycerine or calcium channel blockers as soon as arterial blood pressure parameters allow. Nitroglycerine has been shown to be more effective, less costly, and safer (with a lower incidence of bradycardia and negative inotropy) than intravenous diltiazem.²²² Aspirin (650 mg) is given via suppository within 6 hours of operation and subsequently by mouth at a dose of 100 to 325 mg per day (class I).^{34,223,224} Patients treated concomitantly with clopidogrel are given a slightly lower aspirin dose (81 mg), although no evidence exists for this practice. It is a reasonable alternative to give clopidogrel (75 mg once daily) to patients who cannot tolerate aspirin (class IIa).⁴³ Most patients are extubated within 4 to 6 hours of CABG and discharged from the intensive care unit on the following morning (postoperative day 1). Chest tubes are removed when draining less than 100 mL per 12 hours, when no air leaks, and if the chest x-ray shows no significant residual effusion. Most patients experience surprisingly little postoperative pain, which is managed initially with intravenous narcotics and subsequently with oral codeine or hydromorphone. A short course of nonsteroidal anti-inflammatory drugs is added as an adjuvant in patients with normal renal function and without a history of peptic ulcer or CHF. Beta blockers and other antihypertensive medications are usually restarted at half-dose on the morning following the operation and progressively titrated back to the preoperative dose prior to hospital discharge. Mild to moderate dose statin therapy is now recommended in all patients undergoing CABG, whereas higher doses of statins may be

required to achieve at least a 30% reduction in serum LDL levels. Optimizing glucose control prior to and after surgery with either oral agents or intravenous insulin has reduced the incidence of adverse clinical outcomes. Patients with moderate left ventricular dysfunction (LVEF between 30% and 50%) and normal renal function are started on angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) regardless of symptoms.²²⁵ Our practice is to also start patients with radial or gastroepiploic grafts on daily amlodipine, which is more effective than diltiazem and more specific to the arterial vasculature than nifedipine.^{145,226} Atrial fibrillation prophylaxis varies according to personal surgeon and center preferences²²⁷; our approach consists in maximizing the use of beta blockers early postoperatively. The recent 2011 ACC/AHA guidelines recommend prompt (<24 hours) administration of oral beta blockers to all patients without contraindication to reduce the incidence of postoperative atrial fibrillation (class I).³⁴ Moreover, prophylactic regimens based on the administration of sotalol, amiodarone, and intravenous magnesium have been shown to be effective, although cost-effectiveness remains controversial.²²⁸⁻²³⁰ Patients are discharged home at a median of 5 days postoperatively and in some cases as early as the third postoperative day.

Late Postoperative Period

During the first 3 to 4 weeks after CABG, patients commonly have a poor appetite, insomnia, tiredness, lack of sexual desire, mild neurocognitive deficits, and depressed mood. These phenomena are related to the postoperative state and prove to be transient for most patients; reassurance from the surgeon is often all that is needed. Patients are encouraged to walk progressively as part of convalescence; from a minimum distance of 120 m when discharged from the hospital, patients should progressively increase their daily walking to 1 hour or more by the end of the first postoperative month. Lifting is limited to 3 kg during the first postoperative month, 10 kg during the second month, and 30 kg or less until 6 months after the operation. Structured cardiac rehabilitation programs are a useful adjunct, and patients are encouraged to join as soon as discharged from the hospital. Patients who have a normal convalescence can usually resume driving within 3 weeks of operation and return to work within 2 to 3 months. Patients who have a special occupation in which recurrent cardiac events could put the lives of others at risk (such as bus drivers and pilots) should undergo non-invasive cardiac testing to rule out ischemia prior to resuming work. Despite the invasiveness of CABG, studies looking at the quality of life in patients who participated in the SYNTAX and FREEDOM trials have revealed that quality of life in CABG patients surpasses that of PCI patients after only 6 months.^{231,232}

CABG represents only one of many treatment interventions for patients with CAD, as coronary disease continues to progress. Secondary prevention is essential after CABG: aspirin must be continued, smoking must never be resumed, second-hand smoke must be avoided, exercise must be encouraged, obesity if present must be addressed, lipid profile optimized, and hypertension and

diabetes strictly controlled. These factors have a significant impact on the progression of saphenous vein graft atherosclerosis and, by extension, can also benefit arterial grafts.^{233,234}

Beta blockers are progressively weaned 6 months following uncomplicated CABG in patients with no arrhythmias, no angina, normal ventricular function, and in whom other medications are used for antihypertensive therapy. Amlodipine is discontinued after 1 year in patients with radial or gastroepiploic grafts.²³⁵ Patients with moderate left ventricular dysfunction (LVEF < 40%) should be initiated or continued on ACE inhibitors or ARBs indefinitely, because this is associated with a reduced incidence of cardiac death, acute MI, and clinical heart failure.^{34,225}

RESULTS

Morbidity

The most common complications of CABG are postoperative bleeding, low cardiac output syndrome, MI, neurologic events, renal dysfunction, atrial arrhythmias, and sternal wound infections. Other complications are discussed in detail elsewhere in the book. The definition, incidence, prevention, and treatment of these complications are discussed here.

Postoperative Bleeding and Transfusion

Bleeding after CABG can be attributed to surgical and/or medical causes. Reexploration to control hemorrhage occurs in 2% to 6% of CABG cases²³⁶ and carries a 4.5-fold higher risk of mortality.²³⁷ Predisposing factors for postoperative bleeding and transfusion include advanced age, female gender, lower body weight, preoperative cardiogenic shock, anemia, renal dysfunction (especially dialysis-dependent patients), peripheral vascular disease, poor nutritional status, recent thrombolytic therapy, nonelective cases, repeat operations, and longer CPB times.²³⁷⁻²³⁹ Although this practice is not based on evidence, most surgeons use some variation of the following protocol to guide reexploration: (1) blood drainage from the chest tube more than 400 mL in the first hour after surgery, (2) more than 300 mL/hour in the first 2 hours, (3) more than 200 mL/hour in the first 3 hours, (4) more than 100 mL/hour in the first 4 hours, (5) sudden massive bleeding, (6) signs of cardiac tamponade, and (7) excessive bleeding despite correction of coagulopathy. Surgical causes of bleeding in CABG are usually cannulation purse-string leak, graft anastomosis leak, or bleeding from an ITA branch of stumps.

The medical causes of bleeding can include one or more of the following: depletion of coagulation factors by dilution, activation, and consumption as a result of CPB; quantitative and qualitative platelet abnormalities caused by preoperative antiplatelet medications or renal dysfunction, and the direct effect of CPB; hypothermia, which can impair thromboxane synthesis and suppress platelet aggregation; and residual heparin leading to rebound heparin effect.

Strategies to prevent excessive bleeding after CABG include meticulous surgical technique and hemostasis, prevention or reversal of intraoperative hemodilution, prompt reversal of hypothermia, detection and treatment of residual heparin effect with protamine, blood pressure control, administration of antifibrinolytics, and the use of recombinant activated factor VIIa in severe situations. The latter has been increasingly used in cardiac surgery, but the possibility of bypass graft thrombosis caused by a hypercoagulable milieu remains a theoretical concern.^{240,241}

The incidence of transfusion during primary on-pump CABG ranges from near 0% up to 50% with most centers transfusing approximately 20% of patients.²³⁸ Institution-specific guidelines dictate transfusion thresholds. Preoperative anemia is one of the most important predictors of blood transfusion.²⁴² Studies have shown that both preoperative anemia and perioperative blood transfusions are risk factors for mortality and morbidity including acute kidney injury, wound infections, prolonged ventilation, pulmonary problems, and longer length of stay.²⁴³⁻²⁵⁰ In a large contemporary study of 182,599 patients in the Society of Thoracic Surgery (STS) database,²⁵⁰ preoperative anemia (hematocrit < 33%) had a significant impact on perioperative morbidity and mortality compared to patients with preoperative hematocrit levels higher than 42%. In this study, each 5-point decrease in preoperative hematocrit was associated with 8% higher odds of death, 22% higher odds of postoperative renal failure, and a 10% increase in the risk of deep sternal wound infection. Perioperative blood transfusion was 88.5% in the anemia group compared to 32.5% in the groups with hematocrit levels higher than 42%. Karkouti and associates addressed preoperative anemia with prophylactic transfusion in a pilot trial²⁵¹ and found it did not improve outcomes. This was likely because of the risks of transfusion, which can cancel out the beneficial effects of treating the anemia. Therefore, alternatives to transfusion, such as detecting and managing preoperative anemia from a cause-based approach, must be sought.

Low Cardiac Output Syndrome

Low cardiac output syndrome (LCOS) after CABG is generally defined and accepted as requirement of inotropic medications or IABP insertion to keep systolic blood pressure higher than 90 mm Hg and cardiac index (CI) of more than 2.2 L/min/m² despite optimization of preload, afterload, electrolytes, and blood gas abnormalities for 30 minutes after surgery.²⁵² It occurs in 4% to 14% of isolated CABG cases and carries a 10- to 17-fold increase in mortality and significant increase in morbidity.²⁵²⁻²⁵⁴ Predictors of LCOS include advanced age (>70), female gender, diabetes mellitus, left main and triple-vessel CAD, low ejection fraction (<50%), redo or emergency surgery, recent MI, incomplete revascularization, long CPB time, and poor intraoperative myocardial protection.²⁵²⁻²⁵⁴ Management of LCOS involves thorough assessment of potential causes directed at the modification of correctable causes, such as immediate cardiac and graft catheterization and return to the operating room if necessary. Initially, preload and afterload should

be optimized with appropriate volume infusions and blood pressure control. Contractility may be supported with appropriate inotropic medications. Treating electrolyte and blood gas abnormalities is essential. Hypothermia, if present, must be addressed. An ECG and cardiac enzyme levels must be part of the evaluation to rule out myocardial ischemia or infarction as a culprit. An urgent bedside echocardiogram may be warranted to rule out cardiac tamponade and detect regional wall motion abnormalities if LCOS does not resolve promptly. Evidence supports prophylactic IABP insertion in patients identified preoperatively as at high risk for LCOS.²⁵⁵⁻²⁵⁷ However, IABP may also be inserted postoperatively. In some cases, open chest management may be required for 24 to 48 hours after surgery.²⁵⁸

Perioperative Myocardial Infarction

Perioperative MI occurs in 2% to 10% of first-time CABG cases, depending on the institutional or study definition,^{20,21,259} and carries a higher risk of mortality, morbidity, and reduced long-term quality of life.²⁶⁰⁻²⁶² It may be secondary to graft-related problems or native coronary artery problems. Graft-related problems include kinking and overstretching of the grafts, acute occlusion, technical anastomotic stenosis, or conduit spasm. Causes related to the native circulation include inadequate myocardial protection, incomplete revascularization, and coronary embolization. Insertion of an IABP may be required in these circumstances to minimize myocardial ischemia. Although some elevations in cardiac enzymes are ubiquitous after surgery, elevations in the creatine kinase-myocardial bound (CK-MB) and troponin-I beyond five times the upper normal limit defines a perioperative MI,²⁶³ especially when accompanied by new Q waves or new left bundle branch block on ECG,²⁶⁴ or new regional wall motion abnormalities on transesophageal echocardiography (TEE).²⁶⁵ In a study of 4000 patients by Brener and colleagues,²⁶⁶ elevations of cardiac enzymes above 10 times the upper normal limit was associated with a 30% decrease in survival at 3 years. Inotropes, vasopressors, and the use of an IABP may be helpful in unstable patients; however, cardiac catheterization or reexploration may be needed despite other measures.

Neurologic Events

Neurologic deficit after CABG can be divided into two types: type 1 deficits, which represent major, focal neurologic deficits, stupor, and coma; and type 2 deficits, which are characterized by global deterioration of intellectual function or memory.²⁶⁷ Both types of deficits are likely to be the result of one or a combination of the following: cerebral emboli, hypoperfusion, or inflammation related to CPB. Type I deficits are associated with up to 25% risk of mortality.^{268,269} The incidence of stroke after CABG is between 1.4% and 3.8%.^{270,271} More than half of these occur after surgery, with the remaining occurring intraoperatively.^{272,273} Half of postoperative strokes take place in the first 24 hours after surgery.²⁷⁰ Stroke after CABG carries a mortality of up to 17%, with early (<24 hours) strokes carrying a threefold higher risk of dying

compared with late (>24 hours) strokes.²⁷⁰ Predictors of stroke include advanced age (>70 years), female sex, previous stroke, CHF, atrial fibrillation, diabetes mellitus, hypertension, peripheral vascular disease (including carotid artery disease), renal failure, atherosclerotic aortic disease, and perioperative hypotension or the use of an IABP.^{270,274,275} Although multiple randomized trials did not demonstrate lower prevalence of neurologic injury in off-pump compared with on-pump CABG,²⁷⁶⁻²⁷⁸ one study demonstrated that operative or off-pump techniques that avoided aortic manipulation were associated with fewer intraoperative strokes, which suggests a greater role of aortic manipulation causing stroke compared with CPB exposure.²⁷³ A recent meta-analysis also suggested a significant 30% reduction of stroke in off-pump (1.4%) compared with on-pump CABG (2.1%).²⁷⁹

Type 2 deficits are more difficult to detect and characterize. Delirium occurs in 3% to 50% of patients after CABG, depending on the definition.²⁸⁰ It is generally accepted as a transient disturbance of cognitive function that varies in severity and fluctuates temporally. In addition to causing distress to the patient's family and the health care team, delirium seems to carry long-term consequences such as an increase in mortality.^{281,282} Risk factors of delirium include previous stroke, history of substance abuse, age older than 65 years, perioperative blood transfusion, and perioperative hypotension.²⁸³ Off-pump CABG and preoperative statins may reduce the incidence of postoperative delirium in some cases.^{284,285} Postoperative cognitive dysfunction is common after CABG with an incidence of 30% to 80% at discharge and 20% to 40% six months to 1 year after surgery.^{286,287} It often is difficult to detect, and specialized, targeted testing is needed to reveal the deficits. Despite their common occurrence, they do not seem to be associated with negative long-term consequences.²⁸⁸⁻²⁹⁰

Postoperative Renal Dysfunction

Postoperative renal dysfunction (PRD) is a serious complication of CABG occurring in 7.7% of patients in a large multicenter study, of whom 1.4% required dialysis.²⁹¹ The risk of mortality increases from a baseline of 0.9% to 19% in patients with PRD, and to 63% in patients requiring dialysis. Other studies confirmed these findings²⁹² with one study demonstrating an increased 90-day mortality even with a 50% rise in postoperative creatinine.²⁹³ Furthermore, other groups have shown that PRD is associated with increased rates of cardiovascular events, including the long-term risk of heart failure.^{294,295} Risk factors for PRD, most of which are nonmodifiable, include age older than 70 years, diabetes mellitus, chronic kidney disease, CHF, reoperation, prolonged CPB times, preoperative anemia, perioperative transfusion, and LCOS.^{243,250,291,292} Some propose a more accurate evaluation of renal function through the addition of glomerular filtration rate to serum creatinine after demonstrating the association of occult renal impairment on early and late mortality and cardiovascular events.²⁹⁶ Although off-pump CABG may be associated with a lower incidence of PRD,²⁹⁷ this remains controversial, as some randomized trials have not shown this advantage.^{278,298}

Recombinant human B-type natriuretic peptide given as an infusion during CPB has been evaluated in a randomized trial of 272 patients undergoing CABG.²⁹⁹ Patients receiving the infusion had a significantly lower peak increase in serum creatinine, greater urine output in the initial 24 hours after surgery, shorter length of hospital stay, and lower 180-day mortality. Other studies evaluating human atrial natriuretic peptide have shown similar promising results.^{300,301} Further research will clarify the role of this strategy in protecting the kidneys after cardiac surgery.

Atrial Fibrillation

Postoperative atrial fibrillation (POAF) develops in 20% to 40% of patients undergoing CABG, with a peak incidence on the second and third postoperative days.³⁰²⁻³⁰⁴ It is usually transient and most patients return to sinus rhythm within 2 to 3 days of treatment. However, patients with preoperative atrial fibrillation are unlikely to return to sinus rhythm. The underlying mechanism is not fully understood and is likely multifactorial. A combination of pericardial inflammation, excessive catecholamine production, postoperative autonomic imbalance, interstitial mobilization, volume overload, and alterations in the neurohumoral environment likely contributes to the development of POAF.^{305,306} POAF is associated with a two- to threefold increase in the risk of stroke, increased length of stay, increased cost, and increased mortality.^{302,303,307-309} Predictors for development of atrial fibrillation include advanced age, male sex, smoking, prolonged cross-clamp time, COPD, chronic renal disease, valvular heart disease, atrial enlargement, obesity, prior pericarditis, and withdrawal of beta blockers.^{304,306,310-312}

Treatment of POAF³¹³⁻³¹⁵ begins with correcting electrolyte imbalances, hypoxia, and acidosis. Patients in volume overload may benefit from diuresis when stable hemodynamically. In hemodynamically unstable patients, electrical synchronized cardioversion should be performed. In stable patients, rate or pharmacologic rhythm control strategies should be attempted. Commonly used rate control medications include beta blockers, calcium channel blockers, and digoxin. The latter can be helpful in patients with a depressed left ventricle. Amiodarone is a commonly used medication for pharmacologic rhythm control. Consideration for anticoagulation should be given in patients who remain in atrial fibrillation for 48 hours weighing in the risks of bleeding and thromboembolism.

A recent synthesis from the Cochrane Collaboration, in addition to other reports, looking at preventive strategies for POAF found that beta blockers, sotalol, amiodarone, atrial pacing postoperatively, magnesium, and posterior pericardiotomy reduce the incidence of POAF with variable effectiveness.^{316,317} A recent meta-analysis provides evidence to suggest that preoperative omega-3 supplementation may also decrease the incidence of POAF.³¹⁸

Sternal Wound Infections

Sternal wound infections (SWIs) can be divided into two types: superficial sternal wound infections (SSWIs) and

deep sternal wound infections (DSWIs). The former involves the skin, subcutaneous tissue, and pectoralis fascia and is recognized clinically as the presence of erythema, drainage, fever, or all of these symptoms. The diagnosis of DSWI requires the presence of one of the following: positive culture from mediastinal fluid or tissue; observable mediastinitis during surgery; presence of chest pain, sternal instability, or high-grade fever; and either purulent drainage from the mediastinum or positive blood cultures.³¹⁹ The incidence of SWI is reported to be 0.47% to 8.0% and carries a mortality rate of 0.5% to 9.1%, whereas the incidence of DSWI is 0.22% to 1.97% with a mortality rate of 1.0% to 36%.³²⁰⁻³²²

Microbiologically, *Staphylococcus aureus* and coagulase-negative staphylococci are the most common isolated pathogens.³²³ Reported risk factors for DSWI include advanced age, male sex, COPD, obesity, diabetes mellitus, smoking history, steroid use, renal insufficiency, non-elective surgery, repeat operations, long operative times, reexploration for bleeding, use of bone wax, perioperative transfusion, prolonged hospital stay (>5 days), and the use of bilateral ITAs.^{250,320,324-326} In a recent meta-analysis on this topic,³²⁷ Saso and coworkers concluded that skeletonization of the ITA decreases the risk of all SWIs by 60%, especially in patients with diabetes mellitus, and the advantage is maintained in bilateral ITA harvesting. This is likely because of improved chest perfusion with the skeletonization technique.¹¹⁹ Important steps to prevent SWIs include preoperative showers with chlorhexidine gluconate, prophylactic intranasal mupirocin, hair clipping instead of shaving, intravenous prophylactic antibiotics before skin incision, aggressive perioperative glucose control, skeletonization of the ITA especially when bilateral ITAs are used in obese patients with diabetes or COPD, and strict adherence to sterility.³²⁸⁻³³¹ Although SSWIs may be treated conservatively with antibiotics in most cases, DSWIs commonly require reexploration and débridement of necrotic tissue in the operating room with some cases requiring early vascularized muscle flap coverage.

Mortality

The overall operative mortality of CABG (defined as all in-hospital deaths and all out-of-hospital deaths occurring within 30 days of the procedure) across North American centers that are part of the Society of Thoracic Surgeons database is 3.0%, an improvement since 1990 despite an increase in the mean age of patients (65.1 years), the mean priority status, and the prevalence of comorbid conditions.³³² In the 19,016 patients of the Northern New England Cardiovascular Disease Study Group who received a LITA during CABG, the overall 30-day mortality was 2.4%.³³³ In two contemporary randomized trials, the SYNTAX trial²⁰ and the FREEDOM trial,²¹ the operative mortalities for CABG patients were 3.5% and 1.7%, respectively. These figures are similar to those reported in several other studies.^{111,334}

Predictors of 30-day mortality include high priority of operation, advanced age, female gender, diabetes mellitus, poor left ventricular function (especially in the presence of CHF symptoms), high creatinine level, peripheral

vascular disease, pulmonary disease, and left main CAD.³³⁵ Patients who are younger than 65 and presenting with normal left ventricular function and receiving elective CABG have a 30-day mortality of less than 1%.²⁶⁷

Long-term survival of patients after CABG may depend on the characteristics of the population studied, on the geographic location of the cohort, and on the surgical era, with the impact of secondary prevention programs and arterial revascularization techniques. Most long-term data, however, come from patients who had surgery in the 1970s and 1980s. Long-term vital data of patients enrolled in the CASS registry³³⁶ (who underwent surgery between 1974 and 1979) have shown that survival after CABG in all patients is 96% at 1 year, 90% at 5 years, 74% at 10 years, and 56% at 15 years. Of particular interest in this report, in which arterial grafting was used in only 13% of patients, is that the survival of patients 65 to 70 years or older exceeded that of a matched U.S. population. Sergeant and colleagues³³⁷ reported on 9600 consecutive CABG patients operated on between 1971 and 1993 and found that survival after CABG was 98% at 30 days, 92% at 5 years, 81% at 10 years, 66% at 15 years, and 51% at 20 years. In the final 10-year follow-up of the Bypass Angioplasty Revascularization Investigation (BARI) trial³³⁸ of 914 patients who were randomly assigned to CABG, the survival was 89% at 5 years and 74% at 10 years. The APPROACH registry³³⁹ is a large clinical data collection and outcome monitoring initiative that captured all patients undergoing cardiac catheterization and revascularization in the province of Alberta, Canada, between 1995 and 2000. In 15,392 patients younger than 70 years of age examined in this registry, 4-year adjusted actuarial survival rates for CABG, PCI, and medical therapy were 95.0%, 93.8%, and 90.5%, respectively. Survival rates decreased to 87.3%, 83.9%, and 79.1% for patients 70 to 79 years of age after CABG, PCI, and medical therapy, respectively, and to 77.4%, 71.6%, and 60.3% for patients 80 years of age or older. The SYNTAX trial 5-year follow-up³⁴⁰ reported an all-cause mortality of 11.4% at 5 years for the whole CABG cohort.

Despite the possibility of confounding by indication, evidence suggests that the use of bilateral over single ITA may be associated with improved long-term survival after CABG. Lytle and colleagues reported a risk-adjusted survival of 94%, 84%, and 67% at 5, 10, and 15 postoperative years in 2000 patients who received bilateral ITAs versus 92%, 79%, and 64% in 8100 patients who had a single ITA; an even greater reduction was observed with respect to reoperation rates.¹⁰⁶ Other authors also found that single ITA grafting was a predictor of mortality, late MI, or late reoperation when compared with bilateral ITA grafting (RR = 1.3 [1.1 to 1.6]).^{341,342} A contemporary propensity-matched study demonstrated that bilateral ITAs provided enhanced long-term survival compared with single ITA in patients with normal and reduced LVEF, without increased operative morbidity and mortality.³⁴³ In a meta-analysis of available observational studies, Taggart and colleagues found that the use of bilateral versus single ITA resulted in a hazard ratio for death of 0.81 (95% CI: 0.70, 0.94).³⁴⁴ The benefits of bilateral ITA grafting have also been suggested in the diabetic population.³⁴⁵

Freedom from Cardiac Events

Fundamentally, CABG is performed for two reasons: to improve survival or to alleviate symptoms of angina and prevent nonfatal outcomes such as MI, CHF, and hospitalization. Unfortunately, long-term studies rarely used arterial grafts and lacked structured secondary prevention after CABG. Sergeant and coworkers³⁴⁶ found that the freedom rate from return of angina was 94%, 82%, 61%, and 38% at 1, 5, 10, and 15 years, and that secondary prevention and management of noncardiac comorbidity had the most impact on delaying the return of angina. Freedom from MI was 97%, 94%, 86%, 73%, and 56% at 30 days, 5, 10, 15, and 20 years. Freedom from coronary reintervention, whether PCI or CABG, was 99.7%, 97%, 89%, 72%, and 48% at 30 days, 5, 10, 15, and 20 years. In the BARI trial,³³⁸ freedom from angina was 84% at 5 and 10 years. The freedom from coronary reintervention was 80% at 10 years. In the Arterial Revascularization Therapies Study (ARTS) randomized trial,³⁴⁷ the rates of MI and reintervention at 5 years were 6.4% and 8.8%, respectively. Patients with diabetes mellitus (smaller number) had worse outcomes: their 5-year rates of MI and reintervention were 7.3% and 10.4% compared with 6.3% and 8.4% in patients without diabetes. Arterial grafting probably leads to even better results: in a series of 256 patients³⁴⁸ with triple-vessel disease who received three arterial grafts, the rates for freedom from MI and angina were 97.3% and 85.7% at 7 years, respectively. The SYNTAX trial³⁴⁰ enrolled 1800 patients with triple-vessel or left main CAD across 85 centers. At 5 years, the rates of MI and reintervention were 3.8% and 6.7%, respectively.

Left Ventricular Function

Myocardial ischemia may cause a wide spectrum of myocardial states ranging from viable and functioning, to hibernating, stunned, or scarred and dysfunctional myocardium. The myocardial state and the amount of muscle involved dictates left ventricular function. One of the greatest survival benefits after CABG is in patients with triple-vessel or left main CAD and depressed left ventricular function.^{60,267} If patients exhibit depressed left ventricular function caused by stunned or hibernating myocardium, CABG improves EF by 5% to 18%.^{349,350} These improvements in systolic function appear as early as 2 weeks and endure up to 10 years after surgery, given no cardiovascular events during that time.^{159,351,352} Lack of improvements or deterioration over time is usually related to either incomplete revascularization or graft occlusion. Bax and associates used echocardiography to examine the time course of contractile recovery in stunned and hibernating myocardial PET segments after CABG, and found that 61% of the stunned segments had improved at 3 months, and an additional 9% had improved at 14 months. In contrast, hibernating myocardium segments showed contractile improvement at 3 months in 31% of patients, with a further improvement at 14 months in an additional 61%.¹⁵⁹ Left ventricular diastolic function seems to improve immediately after surgery.³⁵³ Survival of patients with very low LVEF (<20%) range from 59% to 73% at 5 years, with

TABLE 88-3 Reported Conduit Patency in CABG

Conduit	Percentage Patency Based on Duration of Angiographic Follow-up		
	1	5	Late
Saphenous vein graft	84.6% ¹²⁸ 81% ^{*376,425,426} 95% at 6 months ¹⁵³ 94% at 1 yr ³⁷⁷ 98.7% ⁴²⁷	75% ^{*%} ^{*376,425,426} 81% ³⁷⁸ 86.4% ¹³⁰	15 yr: 50% ^{*376,425,426}

CABG, Coronary artery bypass grafting.

significant improvements in heart failure and angina class observed among survivors.^{349,352,354-357}

A recent anterior MI with residual wall-motion anomaly is associated with an intramural thrombus in 31% of patients.³⁵⁸ In contrast, this is much less frequent after an inferior or lateral MI. For these reasons, patients with a recent anterior MI (including a perioperative MI) and significant residual anterior or apical wall-motion abnormality should be anticoagulated for 3 to 6 months after CABG.³⁵⁹

Functional Status and Quality of Life

Quality of life after CABG markedly improves in most patients and may correspond to that of a matched control population.³⁶⁰⁻³⁶² Predictors of suboptimal or worsening quality of life include female sex, low socioeconomic status, smoking, diabetes mellitus, hypertension, low ejection fraction, recurrent angina, and nonenrollment into a cardiac rehabilitation program.^{361,363-365} Improvements in quality of life can be observed at 3 months after surgery, and these improvements seem to endure at least up to 12 years after surgery.^{306,364-366} Although advanced age (octa- and nonagenarians) does not preclude improvements in quality of life, they are less pronounced in this group and may not last in the long term.³⁶⁶⁻³⁶⁸ In contrast to the overall improvement in quality of life and functional status, persistent sexual problems are relatively common after CABG and are most prevalent in men, diabetics, patients with hyperlipidemia, and those with preoperative sexual problems.^{369,370} However, men's sexual satisfaction improved, whereas the women's satisfaction decreased 8 years after surgery.³⁶⁹ Twelve years after CABG, patients had similar improvements in quality of life whether they had on-pump or off-pump CABG.³⁷¹ Contemporary data reveal that quality of life in CABG patients may surpass that of PCI patients as early as 6 months after the intervention.^{231,232}

Graft Patency

In comparison with other forms of revascularization such as PCI, OPCAB, MIDCAB, transmyocardial revascular-

ization, or angiogenic therapy, on-pump CABG has a significant advantage in that its long-term procedural outcome has been well characterized. Multiple long-term angiographic studies have described the patency rates of different types of grafts and risk factors associated with their premature closure (Table 88-3). Early closure (i.e., within 2 to 3 months) of any type of graft is usually because of thrombosis, which develops as a result of hemodynamic factors related to poor graft outflow or technical errors.³⁷² Once the early postoperative period is over, vein grafts start developing a disease complex of their own, namely intimal hyperplasia, which is noted in most grafts as early as 1 month after operation^{372,373} and to which the ITA appears immune.³⁷⁴ This process results in a diffuse concentric reduction in vein graft diameter on angiography, which usually matches that of the native coronary vessel by 1 year after implantation. Intimal hyperplasia can be most significant at suture lines and can lead to anastomotic stenosis in up to 20% of vein grafts. The radial and gastroepiploic arteries have a decreased susceptibility to significant intimal hyperplasia compared with vein grafts, which may translate into better long-term freedom from atherosclerosis and patency considering that intimal hyperplasia usually corresponds to sites that later develop graft atherosclerosis.³⁷⁵ Graft atherosclerosis may be observed in vein grafts as early as 3 to 4 years after operation and has a predilection for areas of intimal hyperplasia. It is characterized by a noncapsulated lipid-rich core that is much more friable than native coronary atherosclerosis.

Saphenous Vein Grafts

The early patency rate of saphenous vein grafts improved markedly in the post-aspirin and post-statin era, with long-term patency data not as extensively characterized as older studies in the pre-aspirin and pre-statin era. Fitzgibbon and associates³⁷⁶ found that vein graft patency was 88% early postoperatively, 81% at 1 year, 75% at 5 years, and 50% at 15 years; when stenosed grafts were excluded, the proportion of nondiseased grafts decreased to 40% at 12.5 years. This corresponded to a vein graft

occlusion rate of 2.1% per year after the initial postoperative period. In the current era, vein graft patency has been found to be greater than 95% at 1 year³⁷⁷ and 81% to 86% at 5 years.^{130,378} The way SVG is handled may influence its patency; one study suggested a 94% patency rate at 3 years in no-touch saphenous veins.^{170,379} Some studies demonstrated a higher patency rate in sequential vein grafts compared to individual ones with up to 76% at 7.5 years for sequential vein grafts and 64.5% for individual vein grafts.^{164,380} This is probably a result of higher graft flow as a consequence of improved distal runoff, which may reduce intimal hyperplasia formation. However, another recent trial showed the opposite conclusion, with SVG to multiple distal targets showing higher failure rates at 1 year.³⁸¹ Although postoperative aspirin is the standard of care, adding clopidogrel to aspirin did not provide increased vein graft patency or reduce the frequency of adverse cardiovascular events.^{377,382}

Internal Thoracic Artery Grafts

Late attrition rates of ITA bypass grafts are low because of the fact that ITA grafts rarely develop significant intimal hyperplasia or late atherosclerosis. Furthermore, the ITA has a potential to grow up to 1.4 times its original size to match the diameter of the coronary artery to which it is anastomosed.³⁸³ Improved pharmacologic therapy and structured secondary prevention programs have improved patency rates in the current era. A 2003 report from the Cleveland Clinic demonstrated a 90% to 95% patency rate of the left ITA anastomosed to the LAD 10 to 20 years after surgery.³⁸⁴ Free ITA grafts likely have comparable patency rates as compared with pedicled ITA grafts, provided that a flawless anastomotic technique is used.³⁸⁵ Some studies report³⁸⁶⁻³⁸⁹ similar patency rates of the RITA compared with the LITA, whether anastomosed to the LAD, circumflex, or right coronary artery, with some suggesting that flow through the RITA may be even greater because of handedness.¹¹⁹ Tatoulis and colleagues³⁸⁷ reported a hierarchy of patency of the RITA depending on the coronary territory grafted (highest patency rates to the LAD and lowest to the right coronary territory). The same authors reported a RITA to LAD patency rate of 95% at 10 years and 90% at 15 years, RITA to circumflex artery patency rate of 91% at 10 years, and RITA to RCA patency rate of 84% at 10 years. They conclude that RITA patency rates are equivalent to LITA for identical territories and are always better than radial arteries and saphenous vein grafts.

Radial Artery Grafts

Acar and coworkers,¹⁵ who are responsible for the revival of the radial artery as a bypass conduit, reported a patency of 83% at 5.6 years in 50 of 910 patients who received a radial artery. Iaco and associates³⁹⁰ reported a 96% 4-year patency in selected patients, with no difference in patency whether the radial was anastomosed to the aorta or to the ITA as a Y-graft. Collins and colleagues¹³⁰ reported radial artery patency of 98.3% based on angiographic data from the RSVP randomized

controlled trial. Tatoulis and coworkers³⁹¹ reported 92.5% patency at 5 and at 7 years. Similar to the RITA, they also showed a hierarchy of patency depending on the coronary territory grafted (highest to the LAD and lowest to the right coronary). Other authors have shown that moderate severity of native target stenosis (70% or less) and grafting to the right coronary artery were associated with lower patency rates and when the radial artery is used in a composite T-graft configuration.¹³⁷ Comparing the mid-term (3-year) angiographic outcomes of the radial artery to those of the saphenous vein, a recent meta-analysis of randomized controlled trials revealed a superior complete graft patency of the radial artery compared with the saphenous vein (88.6% vs. 75.8%; $P = 0.005$), although the radial artery was associated with more string signs.³⁹²

Gastroepiploic Artery Grafts

Late results regarding patency of the gastroepiploic artery as a bypass graft are not as favorable as those of the ITA and radial artery. The 5-year angiographic patency was reported by Hirose and colleagues to be 84%,¹⁵⁰ and 86% at 5 years and 70% at 10 years by Suma and associates.^{151,393,394} Factors associated with premature graft closure include technical anastomotic factors and anastomosis to a less critically stenosed coronary artery in a significant proportion of cases. There has been one randomized controlled trial to date comparing the use of the gastroepiploic artery versus the saphenous vein graft.¹⁵⁵ At 6-month angiographic follow-up, there were no differences in patency between conduits, although it appears that gastroepiploic artery patency is more influenced by competitive coronary flow.¹⁵⁴

CABG versus PCI

A detailed analysis comparing the outcomes following CABG and PCI is beyond the scope of this chapter. No doubt, the benefits of both treatment modalities will evolve along with advances in technology and improvements in conjunctive care. Although initially believed to rid in-stent stenosis, drug-eluting stents have been found to be associated with late stent thrombosis.³⁹⁵

At present, 26 randomized clinical trials have compared CABG with PCI (Table 88-4),^{20-22,351,396-417} with most of these studies releasing subgroup analyses and subsequent longer-term follow-up data. Many of these trials were underpowered to show a significant difference in early survival between PCI and CABG. Most of these trials excluded patients with diabetes, poor left ventricular function, and multivessel disease including left main and proximal LAD disease, for which CABG has been shown to be beneficial. However, the most recent trials began including and addressing these patient populations. Another consideration is that because of strict inclusion and exclusion criteria, only approximately 5% of screened patients were enrolled, which has an impact on the external validity of these trials. For trials that presented follow-up data on an original study cohort, no adjustment in the alpha level was made for repeated

TABLE 88-4 Randomized Controlled Trials Comparing PCI and CABG

Trial Name Study Dates	Stent Use/ DES %	Centers/Patient Number	DM %	LVEF < 50%	3VD	Follow-up Duration (Years)	Author Conclusions	Remarks
Left Main Disease								
PRECOMBAT ⁴¹⁷ 2004-2009	Yes	13/600	32%	Mean 61%	41%	2	PCI noninferior to CABG with respect to MACCE.	Noninferiority margin was wide.
Boudriot ⁴¹⁶ 2003-2009	Yes	4/201	36%	Median 65%	14%	1	PCI inferior to CABG at 12 months for unprotected left main disease.	
LE MANS ³⁹⁶ 2001-2004	Yes/35%	7/105	18%	19%	67%	1	LVEF increase at 1 year in PCI group only.	Actual change in LVEF minimal (3.3 ± 6.7 vs. 0.8 ± 0.8).
Proximal LAD								
Lausanne ⁴⁰² 1989-1993	No	1/134	18%		0%	5	No difference in terms of survival or MACE at 2 years. At 5 years, the incidence of non-Q wave MI and need for repeat procedures was higher in the PTCA group.	
Leipzig ⁴⁰⁰ 1997-2001	Yes/0%	1/120	30%		0%	0.5	No difference in terms of survival or MACE; although CABG was superior in terms of angina relief and need for repeat procedures.	CABG performed via MIDCAB.
Groningen ⁴⁰¹ 1997-1999	Yes	1/102	13%		0%	3	Trend toward improvement in MACE-free survival with CABG; CABG superior in angina relief.	CABG performed via OPCAB.
MASS ⁴⁰⁶ 1988-1991	No	1/214	17%	0%	0%	3	Survival and MACE similar between PCI and CABG at 3 years.	
SIMA ⁴⁰⁴	Yes	6/123	11%	0%		10	CABG superior to PCI regarding the primary composite end of all-cause mortality, MI, and the need for additional revascularization.	
Multivessel Disease								
FREEDOM ²¹ 2005-2010	Yes/100%	140/1900	100%	2.5% EF < 40%	83%	5	For patients with diabetes and multivessel disease, CABG is superior to PCI. CABG has significantly lower rates of death and MI at 5 years compared with PCI.	
CARDia ²² 2002-2007	Yes/69%	24/510	100%	28% (65% had EF)	62%	1	Trial did not show PCI to be noninferior to CABG in diabetic patients at 1 year.	
SYNTAX ^{20,340} 2005-2007	Yes/100%	85/1800	35%	1.9% EF < 30%		5	CABG had lower MACCE rates at 1, 3, and 5 years. CABG remains the standard of care for patients with triple-vessel disease or with left main disease and complex lesions. For patients with less complex lesions and left main disease PCI is an acceptable alternative.	
ARTS ⁴¹² 1997-1998		68/1205	17%	0%	32%	5	At 5 years, no difference in mortality between PCI and CABG; MACCE was higher with PCI.	
ARTS II ⁴³³		606 with DES; compared with ARTS I cohort of 1205	26%		55%	1	DES results in decrease in frequency of repeat procedures with no change in survival or MACE.

TABLE 88-4 Randomized Controlled Trials Comparing PCI and CABG—cont'd

Trial Name Study Dates	Stent Use/ DES %	Centers/Patient Number	DM %	LVEF < 50%	3VD	Follow-up Duration (Years)	Author Conclusions	Remarks
AWESOME ⁴¹¹ 1995-2000	No	16/454 (only 142 randomized)	37%	45%	68%	3	No difference between CABG and PCI in terms of survival or MACE.	
BARI ^{351,434} 1988-1991	No	18/1792	24%	0%	41%	10	CABG superior in terms of survival, angina relief and need for repeat revascularization at 5 years. At 10 years, survival benefit only remained for patients with DM.	
CABRI ³⁹⁷	No	26/1054	0%	12%	40%	4	No difference between CABG and PCI in terms of MACE or survival.	
EAST ⁴⁰⁷ 1987-1990	No	1/392	23%		40%	8	No difference between CABG and PCI in terms of the primary composite endpoint of death, Q wave MI, and a large ischemic defect identified on thallium scanning at 3 years. No difference was observed in terms of survival at 8 years.	CABG superior in terms of angina relief and angiographically determined revascularization at 3 years.
ERACI ⁴⁰⁹ 1988-1990	No	1/127	11%	0%	45%	3	CABG offered greater freedom from cardiac events and greater angina relief compared with PCI.	
ERACI II ⁴⁰⁸ 1996-1998	Yes/0%	7/450	17%		56%	1	PCI superior to CABG in terms of survival.	
ERACI III ⁴¹⁰ 1996-1998 & 2002-2004	Yes/33%	7/675	18%	50%		1	DES more prone to late stent thrombosis than BMS although no difference in survival was observed.	
GABI ⁴⁰⁵ 1986-1991	No	8/359	10%		18%	1	CABG superior to PCI in terms of angina relief and need for repeat procedures; not survival.	
GABI II ⁴³⁵	Yes	8/313				1	No difference between CABG and PCI conducted.	Used a historical surgical cohort.
MASS II ³⁹ 1995-2000	Yes	2/611	29%		58%	5	CABG superior to PCI with regard to the primary composite endpoint of death, Q wave MI, refractory angina requiring revascularization.	
RITA ³⁹⁶	No	16/1011	6%		12%	6.5	No difference between CABG and PCI in regard to survival or MACE.	
SOS ^{436,437} 1996-1999	Yes/0%	53/988	14%		42%	6	CABG superior to PCI in terms of survival and need for repeat revascularization.	
Toulouse ³⁹⁵	No	1/1152	14%		29%	5	CABG superior to PCI in terms of survival, angina relief, and need for repeat procedures.	

BMS, Bare-metal stent; CABG, coronary artery bypass grafting; DES, drug-eluting stent; DM, diabetes mellitus; LVEF, left ventricular ejection fraction; MACE, major adverse cardiac and cerebrovascular event; MACE, major adverse cardiac event; MI, myocardial infarction; MIDCAB, minimally invasive direct coronary artery bypass; OPCAB, off-pump coronary artery bypass; PCI, percutaneous coronary intervention; PTCA, percutaneous transluminal coronary angioplasty; 3VD, triple-vessel disease.

statistical tests. Considering these limitations, a variety of conclusions can be drawn:

1. Although limited data exist comparing unprotected left main stenting (UPLMS) and CABG, UPLMS appears safe in a select patient population. Mid- and long-term results are yet to be established.
2. In the setting of proximal LAD disease, PCI is associated with an increase in the need for repeat revascularization. CABG appears superior in terms of angina relief. Although survival appears similar between CABG and PCI at intermediate follow-up, survival appears superior with CABG in the long term.
3. In patients with triple-vessel disease, CABG provides a survival advantage compared to PCI in patients with intermediate and high baseline SYNTAX scores. CABG is superior to PCI in terms of major adverse cardiac and cerebrovascular events in patients with complex coronary lesions.
4. Diabetic patients derive a survival benefit from CABG, which is maintained over the long term. CABG also reduces the rates of MI compared with PCI.
5. Drug-eluting stents decreased the need for repeat revascularization procedures relative to bare-metal stents; late stent thrombosis with drug-eluting stents does not significantly impact survival compared with bare-metal stents over the long term.

Two contemporary randomized trials were recently completed and contributed further to our understanding of the benefit of PCI with drug-eluting stent versus CABG.^{20,21} The SYNTAX trial²⁰ enrolled 1800 patients with triple-vessel or left main CAD across 85 centers. The primary endpoint of major adverse cardiac or cerebrovascular events at 1 year was higher in the PCI compared with the CABG group (17.8% vs. 12.4%; $P = 0.002$), which was mostly driven by repeat revascularization. The rates of death and MI were similar between the two groups at 1 year, but stroke rates were significantly higher in the CABG group. After 5 years of follow-up, CABG remained superior with regard to the primary outcome. Although the rates of all-cause mortality and stroke were similar between the two groups, the rates of MI, the combination of death or stroke or MI, and cardiac death were all significantly higher in the PCI group. In subgroup analysis, these findings hold true in patients with triple-vessel disease or left main coronary disease and complex lesions (high or intermediate SYNTAX scores for triple-vessel disease and high SYNTAX scores for left main coronary disease). For patients with less complex lesions (low SYNTAX scores for triple-vessel disease and intermediate or low SYNTAX scores for left main coronary disease), PCI may be an acceptable alternative. In triple-vessel disease, the benefit of CABG over PCI with regard to cardiac death was almost twofold ($P = 0.0008$ for intermediate SYNTAX score and $P = 0.0005$ for high SYNTAX score).³⁴⁰

The FREEDOM trial^{20,21} enrolled 1900 patients with diabetes and multivessel coronary disease across 140 centers. CABG was superior to PCI in that it significantly reduced the rates of death from any cause and MI at 5 years at the cost of significantly higher stroke rates in the CABG group. The conclusions did not change across

prespecified subgroups including low, intermediate, and high SYNTAX scores, LVEF <40% and ≥40%.

Although randomization protects against confounding and selection bias, the main problem with randomized studies of CABG versus PCI is generalizability as a result of their nonrepresentativeness and the small proportion of the screened patients who are actually enrolled. The results of seven large registries are more useful for looking at the comparative *effectiveness* of CABG versus PCI in a particular population setting. These registries are the New York State PCI and CABG registries,⁴¹⁸ which compared more than 60,000 patients; the Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease (APPROACH) registry,³³⁹ which examined approximately 16,000 patients after CABG or PCI; the Northern New England Cardiovascular Disease Study Group Registry,⁴¹⁹ which examined 2766 patients with diabetes; the Duke registry,⁴²⁰ which examined approximately 7000 patients who underwent CABG versus PCI; the DELTA registry,⁴²¹ a multicenter registry evaluating left main coronary artery treatment with PCI versus CABG in 2,775 patients; the CREDO-Kyoto PCI/CABG registry cohort 2, a Japanese registry⁴²² of approximately 16,000 patients with first coronary revascularization; and the CUSTOMIZE registry,⁴²³ which examined approximately 900 patients undergoing PCI versus CABG in unprotected left main disease. Because these studies are observational, the possibility of selection bias (confounding by indication) remains despite accounting for simple confounding via multivariable analyses. Nevertheless, the results of these studies are worth examining and can be summarized as follows:

1. Stenting unprotected left main CAD may be an option in low and intermediate SYNTAX scores and in older adult patients (>75 years old), with the greater risk of repeat revascularization. In high SYNTAX score lesions, CABG remains the gold standard.
2. Three-, four-, and five-year risk-adjusted survival after CABG is superior to PCI for patients with triple-vessel disease in all study participants (regardless of diabetic status or left ventricular function).
3. Patients with high-grade proximal LAD stenosis benefit from CABG over PCI.
4. Superiority of CABG over PCI in diabetic patients is confirmed.
5. There might be an increased benefit of choosing CABG over PCI in older adults; in any case, older adult patients may benefit the most from revascularization over medical therapy for CAD.
6. CABG is superior to PCI with drug-eluting stents in terms of survival, angina relief, and need for repeat procedures.⁴²⁴

CONCLUSION

Coronary artery bypass grafting remains the most durable method of coronary revascularization available today. Its future is exciting and should be directed at further development and research to evaluate the role of routine complete arterial grafting, minimally invasive techniques,

hybrid coronary revascularization strategies, secondary prevention programs, and adjunct pharmacotherapeutic strategies in achieving the ultimate goal of cardiac surgeons: making CABG a near-zero risk, infallible, and permanent method of coronary revascularization.

Mechanism

CONCLUSION

In 1967, Sabiston and colleagues reported the first clinically successful coronary artery bypass graft (CABG) operation. Other early pioneers include Favaloro, who is credited with popularizing the use of autogenous saphenous vein, and Kolesov, who performed the first mammary artery to coronary artery anastomosis. Over the next several years, centers around the world began performing CABG procedures in large numbers. Subsequent refinements in cardiopulmonary bypass (CPB), the introduction of cardioplegia, the growing acceptance of the left internal mammary artery graft, and the development of the intra-aortic balloon pump (IABP) resulted in continued improvements in outcomes after CABG. By the early 1990s, more than 350,000 CABG procedures were being performed each year in the United States alone, with routine application in octogenarians, patients with severely impaired ventricular function, and patients with serious noncardiac morbidities.

As results continued to improve, and as mortality and major morbidity rates in the 2% range became

commonplace, many surgeons turned their efforts toward decreasing the invasiveness of CABG and exploring alternative strategies of revascularization. Over the past several years, this effort has produced a number of new technologies, techniques, and variations on traditional CABG—all intended to avoid CPB, minimize aortic manipulation, improve graft patency, and reduce the trauma of surgical access. These variations include multivessel CABG without CPB, single-vessel CABG without CPB via a left mini-thoracotomy, videoscopic single-vessel CABG using surgical robotics, and multivessel CABG via a left mini-thoracotomy using peripheral cannulation and CPB. Other new procedures include transmyocardial revascularization, reoperative CABG through alternative incisions, and grafting strategies and devices that minimize or eliminate aortic manipulation, facilitate construction of the distal anastomosis, and perhaps improve long-term graft patency. This chapter describes these developments, discusses their relative merits, and summarizes current clinical results.

CARDIOPULMONARY BYPASS

The development of the heart-lung machine by Gibbon and its early application by Kirklin initiated the era of open heart surgery, which eventually made CABG possible. CPB and the subsequent introduction of cardioplegia provided a motionless, blood-free surgical field, which enabled the precision and reproducibility necessary for direct coronary anastomosis. Despite the obvious benefits of CPB, however, there is an increasing awareness of its potential deleterious effects. As the formed elements of the blood contact the various components of the heart-lung machine, the blood elements are activated, resulting in a number of hematologic and ultimately systemic changes. Typical sequelae include activation of complement, release of endotoxin, activation of leukocytes, increased expression of adhesion molecules, and release of inflammatory mediators, including cytokines, arachidonic acid metabolites, free radicals, and other components.¹ These sequelae occasionally manifest as coagulopathy, third-space fluid retention, and subtle end-organ dysfunction, including neurocognitive changes. The magnitude of this systemic inflammatory response is generally modest but can be quite severe, especially when the CPB time is prolonged. Furthermore, a small percentage of patients with preoperative end-organ dysfunction sustain significant morbidity when subjected to even a moderate systemic inflammatory response.

Ongoing efforts have been directed at reducing the magnitude of the systemic inflammatory response associated with CPB. These efforts include decreasing the surface area and modifying the surface composition of the CPB circuit to minimize surface activation, reducing hemodilution by decreasing the volume of crystalloid prime needed to institute CPB, avoiding the use of a cardiotomy sucker, and pretreating patients with various anti-inflammatory medications, such as aprotinin.² Despite progress in these areas, performing CABG without CPB remains attractive.

MULTIVESSEL OFF-PUMP CORONARY ARTERY BYPASS

Off-pump coronary artery bypass (OPCAB) grafting is as old as coronary surgery itself. Large case series dating back to the 1970s document its feasibility.³⁻⁵ Nevertheless, OPCAB only recently gained widespread acceptance and entered the mainstream of clinical practice, propelled by a greater awareness of the potential morbidity of CPB and aortic manipulation and facilitated by improvements in surgical tools and techniques. OPCAB is part of the procedural armamentarium of a growing proportion of surgeons worldwide, and it can be performed in virtually any patient requiring coronary revascularization.

The introduction of self-retaining coronary stabilizers and the development of techniques for their use are key factors that have led to resurgent interest in OPCAB. When properly used, coronary stabilizers provide a relatively motionless and blood-free field, similar to that provided by CPB. The subsequent introduction of self-

retaining cardiac positioning devices and the evolution of surgical techniques for rotating the heart enabled precise anastomoses to be constructed on the inferior, posterior, and lateral walls of the beating heart while maintaining adequate hemodynamic values without CPB.

Self-Retaining Coronary Stabilizers

A number of coronary artery stabilizers are available for clinical use. Current stabilizers can be categorized as compression, suction, or capture devices, depending on their design. When used properly, each type provides excellent immobility.

Compression-type stabilizers are generally two-pronged forks that are placed lightly on the epicardial surface so that the prongs are parallel to, and flanking, the coronary artery at the intended anastomotic site. The undersurface of the prongs provides traction to avoid slippage. The fork is attached to the retractor via an articulating arm and can be locked tightly in position once the desired position has been achieved. Generally, the best stability occurs when only light downward force is exerted on the surface of the heart. Paradoxically, an increase in motion occurs when excessive downward force is applied. One should use the exposure techniques described later in this chapter to present the target artery before positioning the stabilizer rather than relying on the stabilizer to retract the heart. Compression-type stabilizers are advantageous in that they may be set up quickly and simply and have an extremely low profile that allows unrestricted access to the coronary artery. For some aspects of the heart, however, compression stabilizers may require slightly more downward pressure to avoid slippage (Fig. 89-1).

Suction-type stabilizers also are generally two-pronged forks attached to the retractor by means of an articulating arm. These stabilizers, however, are constructed with a series of ports on the undersurface of the prongs, which are connected by sterile tubing to a -100 to -300 mm Hg wall-suction unit. The epicardium and epicardial fat that

FIGURE 89-1 ■ Compression-type stabilizers generally have a low profile and a textured bottom surface that improves their ability to grip the epicardium.

flank the vessel are sucked into these ports, allowing the stabilizer to grip the surface of the heart. Thus, less downward force is required at the anastomotic site. Suction stabilizers are set up quickly but require a regulated vacuum line. They have the added advantage of providing traction and countertraction of the fat surrounding the coronary artery, so they are well suited for arteries deep within the fat. Suction stabilizers tend to have a slightly higher profile than compression types, but access to the coronary artery is not generally problematic (Fig. 89-2).

Capture-type stabilizers are usually fenestrated platforms that frame the intended anastomotic site. Silicone elastic tapes are passed deep under the coronary and locked to the platform under tension, pulling the epicardium up against the platform's undersurface (Fig. 89-3A). Like suction, this effect reduces the demand for downward force to prevent slippage. Capture stabilizers, by virtue of their circumferential effect, provide superior anastomotic stability.⁶ Additionally, the silicone elastic tapes compress the coronary against the platform's posterior aspect, providing integrated biplane coronary occlusion (see Fig. 89-3B). Capture stabilizers are arguably more complex to position, however, and require proper spacing and alignment of the silicone elastic tapes to ensure adequate hemostasis. Furthermore, because of their larger size, they may not be well suited for use during construction of tightly spaced sequential anastomoses.

Preventing Hemodynamic Compromise during Multivessel OPCAB

One of the greatest challenges of the early OPCAB procedures was to maintain hemodynamic stability while grafting coronaries on the lateral and posterolateral aspects of the heart. This challenge was greatest in patients with poor ventricular function and marginally compensated ischemia. The problem has been largely eliminated by advances in surgical technique, including placement of deep pericardial retraction sutures, right vertical pericardiotomy and pleurotomy, and right hemisternal elevation, as well as the introduction of cardiac positioning devices and advances in anesthetic management. To understand how these tools and techniques minimize the adverse effects of cardiac manipulation, it is important to understand the causes of potential hemodynamic compromise during OPCAB.

FIGURE 89-2 ■ Suction-type stabilizers use a series of suction cups to grip the epicardium. Although they have a slightly higher profile than compression-type stabilizers, they often require less downward force than compressive footplates.

Left Ventricular Compromise

When a coronary stabilizer is positioned by using excessive downward force, the stabilized aspect of the heart is constrained, leading to diastolic dysfunction and a decreased left ventricular end-diastolic volume (LVEDV), stroke volume, and cardiac output.⁷ Whereas volume loading and Trendelenburg positioning attenuate these effects by elevating left ventricular (LV) filling pressures, recourse to these methods carries a risk of exacerbating intraoperative third-space fluid sequestration and associated morbidity. Similarly, the use of short-acting α -adrenergic agents can effectively maintain perfusion pressure in this setting, but they may be associated with an increased risk of perioperative mesenteric ischemia.⁸ β -Adrenergic agents should similarly be avoided in the setting of yet-to-be-grafted coronary arteries. There are also anecdotal reports of severe mitral regurgitation during exposure of the lateral wall, possibly related to deformation of subvalvular structures in combination with coronary insufficiency. Exposure techniques that minimize or eliminate LV deformation are therefore desirable.

Right Ventricular Compromise

Exposure of the lateral LV wall displaces the heart toward the right, compressing the right ventricle against the pericardium and right side of the sternum. The relatively low pressure in the right ventricle makes that chamber

FIGURE 89-3 ■ Capture-type stabilizers use silicone elastic tapes to ensure tight apposition of the textured surface of the footplate and the epicardial surface. This arrangement results in integrated coronary compression. **A**, The surgeon's view of a coronary vessel in a capture-type stabilizer demonstrating spacing of the silicone elastic tapes. **B**, Simulated view of the coronary vessel segment from the underside of the stabilizer.

particularly vulnerable to deformation and reduction of the right ventricular end-diastolic volume (RVEDV).^{9,10} The decreased right ventricular (RV) stroke volume leads to poor LV filling and a decrease in cardiac output. Volume loading and use of the Trendelenburg position can compensate for this effect, as noted in the previous paragraph, but not without potential risk. RV compromise is thought to be the dominant cause in many cases of hemodynamic instability that occurs during exposure of the lateral wall. Various groups have proposed the use of RV assistance as palliation for RV compromise during multivessel OPCAB.^{11,12} Clearly, however, exposure techniques that minimize RV deformation are desirable.

Myocardial Ischemia

Intraoperative myocardial ischemia, secondary to decompensated coronary disease, transient coronary snaring during grafting, or poor perfusion pressure during heart manipulation, is another mechanism that leads to hemodynamic instability. This complication is best prevented by close communication with the anesthesiologist, a revascularization strategy that minimizes myocardial ischemia, and exposure techniques that maintain hemodynamic stability. Whereas each patient should be managed on an individual basis, useful axioms exist. Patients with significant left main stenosis and marginally compensated ischemia may benefit from completion of the left internal mammary artery (LIMA) to left anterior descending (LAD) graft before manipulation of the heart. Similarly, initial revascularization of occluded, collateralized coronary arteries should be carried out before one transiently occludes the vessels that supply collaterals to those arteries. Selective use of intracoronary shunts, aortocoronary shunts, or assisted coronary perfusion devices¹³ can be essential when grafting a moderately stenosed right coronary artery (RCA) proximal to the origin of the posterior descending branch, or when grafting the proximal portion of a moderately stenosed LAD (Fig. 89-4). The judicious use of an intra-aortic balloon pump can occasionally prove invaluable.¹⁴

FIGURE 89-4 ■ A small, flexible, olive-tipped shunt inserted in the distal coronary artery (B) is attached to a short extension of IV tubing connected to a small cannula in the ascending aorta (A) to provide uninterrupted blood flow to the distal coronary bed while the anastomosis is constructed.

Exposure Techniques

Depending on the size and shape of the heart and the dimensions of the chest cavity, visualization of the proximal obtuse marginal and posterolateral branches of the circumflex system may be obstructed by the left hemisternum. Although intuitive attempts at improving exposure may involve applying additional rightward force to that aspect of the heart with the stabilizer, this maneuver frequently leads to hemodynamic compromise and paradoxically poor stabilization. Maximal access and stability at the anastomotic site with minimal compromise of cardiac performance is most readily achieved when the stabilizer is applied with little or no pressure; thus, this device should be used only to stabilize the anastomotic field rather than to assist in retracting the heart. In many patients with relatively normal hearts and readily accessible coronaries, little attention to exposure techniques is required. In contrast, during multivessel OPCAB on patients with large, poorly contracting hearts, attention to these techniques is essential. In these patients, exposure of the lateral cardiac wall is best achieved with deep pericardial sutures, a right pleurotomy and pericardiotomy, right hemisternal elevation, or apical suction devices, as described next.

Deep Pericardial Sutures

One of the most important advances in exposure techniques for OPCAB is the use of deep pericardial sutures. First described by Lima,¹⁵ these sutures, when placed under tension, create a ridge of pericardium that supports the base of the lateral left ventricle adjacent to the atrio-ventricular groove and allows the heart to be rotated rightward to assume an “apex up” position (Fig. 89-5). In this subluxed position, the apex of the heart points toward the ceiling and protrudes through the sternotomy incision, often above the plane of the sternal retractor. This generally allows adequate exposure of the lateral and inferior aspects of the left ventricle before the coronary stabilizer is applied.

Placement of deep pericardial sutures may vary among surgeons and according to the patient's anatomy. Generally, one or two 2-0 silk sutures are placed in the

FIGURE 89-5 ■ Deep pericardial sutures secured under tension deliver the heart into an “apex up” position that provides adequate exposure of the lateral wall in many patients.

pericardium posterior to the left phrenic nerve and immediately anterior to one or both left pulmonary veins; one suture is placed deep in the oblique sinus behind the left atrium, and one is placed to the left and posterior to the inferior vena cava (Fig. 89-6). Care must be taken to avoid injury to underlying structures, such as the esophagus and lung.¹⁶ The suture in the oblique sinus is particularly important for obtaining good exposure of the lateral wall near the base of the heart. One commonly used technique consists of placing a single deep pericardial suture in this location, then using that suture to secure the midpoint of a 50-cm gauze strip deep in the oblique sinus. Subsequent traction on the two ends of the strip can be adjusted to optimize exposure of different surfaces of the heart.

Regardless of the technique used, deep pericardial traction sutures generally allow presentation of the lateral, inferior, and even posterior wall of the heart with little change in LV geometry or LVEDV, providing adequate access for multivessel CABG while maintaining hemodynamic stability. In some patients, however, some or all additional maneuvers discussed in the following paragraphs are necessary to accomplish this aim.

Right Pleurotomy and Right Vertical Pericardiotomy

A right pleurotomy and right vertical pericardiotomy are helpful technical adjuncts when lateral wall exposure is difficult. Human pericardium is quite flexible but very inelastic. This inelasticity accounts for the profound hemodynamic effects caused by acute tamponade despite a relatively small volume of intrapericardial fluid. The posterior pericardium, right lateral pericardium, and diaphragmatic pericardium constitute a fixed-volume cusp or pocket. It is into this pocket that the right ventricle is compressed during extreme rightward rotation of the heart. In effect, pressure on the left ventricle results in RV tamponade. Opening the right pleura widely and incising the pericardium will vent the pocket, allowing the heart to herniate into the right pleural space while maintaining the RVEDV.

A right lateral pericardiotomy can be performed by making a right vertical incision that extends from the cut edge of the initial anterior pericardiotomy, 2 cm cephalad and parallel to the diaphragm, down to the level of the inferior vena cava, with care to avoid injuring the right phrenic nerve (Fig. 89-7). The 2-cm rim of pericardium on the diaphragm facilitates closure of the pericardiotomy once grafting is complete. Caution should be exercised in measuring right-sided grafts, as closure of the lateral pericardial incision may affect how they lie. Many surgeons advise closing the lateral pericardiotomy before constructing the proximal anastomosis of a right-sided graft to ensure a tension-free non-kinking graft. In some circumstances, one may also benefit from removing the right pericardiophrenic fat pad, which can be large, and decreasing the tidal volume to provide additional room for the easily deformed right ventricle. These techniques offer some benefit in almost all patients but are extremely valuable in obtaining lateral-wall access in patients with enlarged hearts and marginal hemodynamic stability.

Some surgeons skilled at performing the OPCAB procedure avoid a right pleurotomy and lateral pericardiotomy. These surgeons contend that incising the lateral pericardium and entering an additional body cavity is inconsistent with the objective of decreased invasiveness. Many patients can indeed be treated successfully without this maneuver. In our opinion, however, it facilitates the reproducible performance of a precise anastomosis during multivessel OPCAB. Furthermore, a right pleurotomy neither leaves a scar nor is associated with significant morbidity or additional length of hospital stay.

Right Hemisternal Elevation

In conjunction with the techniques described earlier, asymmetrical right hemisternal elevation can further improve lateral wall exposure. Once the right pericardium and pleura are incised, the right half of the sternum and right blade of the retractor limit rightward displacement of the subluxed apex of the heart. By elevating these structures, the surgeon can cause the apex to clear the posterior aspect of the chest wall. This allows the entire

FIGURE 89-6 ■ The diagram shows the approximate locations for the deep pericardial sutures. Most surgeons agree that the suture at B is of greatest importance for lateral wall exposure. The photograph shows operative exposure for placement of the deep pericardial sutures, with the heart reflected up and to the right.

FIGURE 89-7 ■ **A**, An L-shaped pericardiotomy is created to the right of midline with the horizontal component extending to the cardiac apex. The right pleural space is opened widely and the right pericardium is excised almost to the inferior vena cava with care to avoid the right phrenic nerve. **B**, These incisions will vent the pocket, allowing the heart to herniate into the right pleural space to minimize hemodynamic compromise.

heart to rotate into the right pleural space with little change in LV and RV geometry and RVEDV (Fig. 89-8). As a result, the proximal obtuse marginal and posterolateral branches are brought toward the center of the operative field and into the surgeon's view.

Right hemisternal elevation is best carried out as the sternotomy incision is being performed. If anterior traction is applied on the right-sided chest wall when the retractor is first spread, costal microfractures that inevitably form during sternal opening will occur predominantly in the right-sided ribs. The resulting increase in flexibility of the right-sided chest wall will subsequently prevent the need for exaggerated tilting of the sternal retractor, which is often required to overcome the tendency of the left-sided chest wall to rise after internal mammary artery harvest. The diaphragmatic insertion on the inferior aspect of the right hemisternum can also be released to facilitate right hemisternal elevation and create additional room for displacement of the cardiac apex into the right pleural space.

Apical Suction Devices

Self-retaining apical suction retractors have been added to the operative armamentarium of OPCAB surgeons. These tools are used to position the heart for exposure of its lateral and posterior surfaces with little impact on hemodynamic values. The retractors generally consist of a suction cup mounted at the end of an articulating arm that can be locked in position relative to the retractor (Fig. 89-9). The suction cup is placed at or near the apex of the heart and is held in position by a vacuum (300 mm Hg). Pulling the apex away from the base and pivoting the cardiac axis can achieve excellent exposure with little impact on LV geometry and the LVEDV. Although use of these devices adds to the expense of OPCAB, their easy affixation and rapid set-up make them an attractive adjunct for use in challenging cases. In many OPCAB centers, apical suction retractors, in conjunction with a right pleurotomy, vertical pericardiotomy, and sternal tilt, are used in most cases (Fig. 89-10).

FIGURE 89-8 ■ Tilting the right hemisternum, performing a vertical pericardiotomy, and opening the right pleura often allows the surgeon to position the apex of the heart in the right side of the chest. The cardiac apex (**A**) is deep to the right hemisternum, and the left atrial appendage (**B**) is brought to the center of the operative field. This results in optimum exposure of the lateral wall, especially in patients with cardiomegaly.

Results after OPCAB

The relative merit of OPCAB versus CABG with CPB remains unclear. Few topics in cardiac surgery have given rise to more debate. Since the 1990s, when interest in OPCAB was renewed, researchers have attempted to clarify the ideal role of this treatment modality. Early reports from retrospective, nonrandomized, multicenter series showed lower death and stroke rates, less need for IABP use and postoperative transfusion, and a shorter ventilator time and length of hospital stay for OPCAB than for contemporaneous conventional CABG performed at the same institutions¹⁷⁻²⁴ or recorded in national databases.^{25,26}

These encouraging results led to a number of early prospective, randomized trials, many of which showed no difference between OPCAB and CABG with CPB with regard to mortality, myocardial infarction, or coronary reintervention.²⁷⁻³¹ Early meta-analyses^{32,33} and systematic reviews³⁴ confirmed these results. For years, the use of OPCAB continued to increase. One national, multicenter, observational study showed a peak in 2003, almost one quarter of cases being performed off pump.³⁵ Increasing interest and ongoing international debate continued to drive intense clinical investigation.

FIGURE 89-9 ■ Apical suction devices allow the surgeon to rapidly position the heart without placement of deep pericardial sutures.

In 2009, the Veterans Affairs Randomized On/Off Bypass (ROOBY) trial investigators reported the first large, multicenter, prospectively randomized study.³⁶ More than 2000 patients were enrolled, and the results sparked intense debate. Patients undergoing OPCAB had a significantly higher rate of the composite endpoint, including all-cause mortality, nonfatal infarction, and repeat revascularization procedures at 1 year. Closer analysis of the follow-up angiography data revealed that OPCAB resulted in lower rates of FitzGibbon A patency and of effective revascularization.³⁷ Furthermore, ineffective revascularization was associated with significantly higher rates of adverse cardiac events.

Shortly after the ROOBY trial results were published, several worldwide groups of investigators began to report their own findings. The German Off-Pump Coronary Artery Bypass Grafting in Elderly Patients (GOPCABE) study was another prospective, large-cohort, multicenter trial that focused on patients 75 years of age and older.³⁸ Again, more than 2000 subjects were randomized to undergo either OPCAB or CABG with CPB. The investigators reported no significant difference in the composite or individual outcomes of death, stroke, infarction, or new renal-replacement therapy at 30 days or at 1 year.

These trials were subjected to intense debate and criticism. Objectors noted that the trials had enrolled too few patients, thereby lacking sufficient statistical power to detect differences in certain clinical endpoints. The technical expertise of the surgeons who performed OPCAB in these trials was also brought into question. To address these potential limitations, Canadian investigators reported initial data from their multicenter, prospective trial, which randomized almost twice the number of patients to undergo OPCAB or CABG with CPB.

The CABG Off or On Pump Revascularization Study (CORONARY) was more effectively powered than previous trials, and participating surgeons were required to have at least 2 years of experience involving more than 100 procedures performed. At 30 days and 1 year, the CORONARY trial showed no significant differences in the rate of primary composite outcome or its individual components, which included death, nonfatal stroke, nonfatal myocardial infarction, or new renal failure requiring dialysis 30 days after randomization.^{39,40} The OPCAB

FIGURE 89-10 ■ **A**, An apical suction device, when it is used in conjunction with right hemisternal elevation, a vertical pericardiotomy, and a right pleurotomy, provides optimal exposure of the high lateral wall. **B**, A vein graft constructed without CPB from the descending thoracic aorta to lateral wall vessels through a left thoracotomy avoids some of the technical challenges associated with reoperative CABG in patients with patent mammary artery grafts.

patients had shorter operations and ventilator times, fewer blood-product transfusions, fewer repeat operations for bleeding, and lower rates of respiratory complications and acute kidney injury. However, fewer bypass grafts were completed in the OPCAB group, and the rates of incomplete revascularization were higher. Similar findings regarding fewer numbers of grafts and lower rates of revascularization have been reported in other trials, and these factors are thought to contribute to the inferior long-term outcomes of OPCAB.⁴¹ Five-year follow-up data from the CORONARY trial are anticipated and should provide further evidence for the appropriate use of OPCAB in multivessel CAD.

Although the debate continues, there is still compelling evidence that OPCAB is associated with decreased operative risk in some high-risk groups,^{17,42,43} including older patients, those with a reduced ejection fraction, and those with renal failure.⁴⁴⁻⁴⁷ Several reports have documented that OPCAB is associated with a decreased risk in reoperative patients as well.⁴⁸⁻⁵¹

Because reoperative OPCAB can be performed frequently without dissecting out the ascending aorta or manipulating diseased grafts, it is an attractive approach. However, many surgeons consider the presence of heavily diseased but patent vein grafts a contraindication to OPCAB because of the risk of atheromatous embolization down the grafts while the heart is being repositioned. A tailored left thoracotomy approach has been reported for reoperative grafting of the lateral wall in patients with patent LIMA-to-LAD grafts. Using this exposure, the surgeon can readily construct a graft from the descending thoracic aorta to lateral wall branches while avoiding the technical challenges associated with LIMA-graft mobilization. Long-term patency data are not available for this type of graft. Similarly, lower sternotomy and upper abdominal incisions have been described for constructing grafts to the inferior wall with the right gastroepiploic artery.^{52,53}

Although no consensus as yet exists, it is generally agreed that a well-performed OPCAB procedure is superior to a poorly performed conventional CABG operation and vice versa. Furthermore, there are many patients in whom OPCAB would be technically difficult or inadvisable (because of a deep intramuscular LAD, small diffusely diseased coronaries, need for an extensive endarterectomy, or active ischemia associated with hemodynamic compromise); there are also many patients for whom conventional CABG would pose an unnecessary risk (because of an atheromatous ascending aorta or a systemic disease process that might be exacerbated by CPB). Familiarity with the tools and techniques outlined here and the ability to perform OPCAB when necessary are valuable resources for practicing cardiac surgeons.

Minimizing Aortic Manipulation

Most surgeons agree that OPCAB is ideally suited for revascularization in patients with significant atheroma or calcification of the ascending aorta. In this setting, free grafts constructed from either the right internal mammary artery or the right radial artery can be attached to the side of the in situ LIMA, as described initially by Tector

and colleagues,⁵⁴ and used to perform multivessel OPCAB without manipulating the aorta. Occasionally, the innominate artery can be used as a site for a proximal anastomosis if that artery is free of atheromatous plaque.

Alternatively, free grafts can be attached to a small disease-free area of the aorta with an automated anastomotic device (AAD), which obviates the need for a partial-occlusion clamp (Fig. 89-11). In 2008, the Food and Drug Administration (FDA) cleared these devices for sale in the United States. Although a previous AAD for constructing a clampless proximal anastomosis was approved for U.S. sale in 2001, it was subsequently withdrawn from the market when longer term data suggested that it was associated with decreased graft patency. In contrast, the latest iteration of an AAD for proximal use seems to be associated with equal or improved long-term graft patency when compared to a hand-sewn technique.⁵⁵ Although it is compelling to hope that AADs will improve outcomes by decreasing aortic manipulation, this has yet to be demonstrated in a case-control study. It is clear, however, that the current device allows a widely patent proximal anastomosis to be rapidly constructed without a partial-occlusion aortic clamp; moreover, the AAD can be readily used in patients who have areas of ascending aortic plaque that would make application of a partial-occlusion clamp unwise. The ultimate role of proximal AADs in the evolution of CABG surgery will depend on a number of issues, not least of which are economic ones.

Since 2002, several tools have been available that facilitate construction of a hand-sewn proximal anastomosis between a free graft and the ascending aorta without requiring a traditional partial-occlusion clamp.⁵⁶⁻⁵⁹ Although slightly more labor intensive to use than loading and deploying a proximal AAD, these aortotomy occlusion tools permit construction of a tailored, hand-sewn anastomosis and accommodate a wider range of potential conduits, including radial and free-mammary grafts. These tools require a greater degree of technical facility than does a partial-occlusion clamp, but they decrease aortic manipulation and, like AADs, can be used when aortic plaque would make applying a partial-occlusion clamp ill advised. Using a combination of palpation and epiaortic ultrasonography, the surgeon can frequently identify an appropriate dime-sized area of relatively normal aorta where the occlusion device can be deployed. Although devices of this sort have been shown to liberate fewer gaseous and particulate emboli than do partial-occlusion clamps,⁶⁰ there are no compelling data to show that aortotomy occlusion tools are associated with improved outcomes. Nevertheless, these tools allow OPCAB to be readily performed while avoiding the hazards of cannulation and cross-clamping of the diseased ascending aorta.

Neurocognitive Dysfunction after OPCAB

Numerous published reports have described the new onset of subtle neurocognitive dysfunction (NCD) in some patients after CABG. Depending on the sensitivity of the tests used, the incidence has been reported to be

FIGURE 89-11 ■ **A**, An automated device for performing the proximal anastomosis between the ascending aorta and the saphenous vein without a partial-occlusion clamp was approved for clinical use in 2008 after demonstration of intermediate patency equivalent to hand-sewn anastomosis. **B-E**, Tools that facilitate construction of the proximal graft-to-aorta anastomosis without a cross-clamp and automated anastomotic couplers may have an impact on the incidence of neurocognitive deficit after CABG.

5% to 60%. Specific deficits include short-term memory loss, reduced ability to perform simple calculations, and disturbances in personality and mood.⁶¹⁻⁶³ Many CPB-related factors, including a systemic inflammatory response, alterations in cerebral blood flow, and microemboli—either arising from the CPB circuit or related to cannulation and cross-clamping—have been implicated.^{63,64} Several groups have reported that OPCAB is associated with a significantly milder systemic inflammatory response.^{44,65,66} The magnitude of the response, however, has not been shown to correlate with the severity of NCD in individual patients.¹ Furthermore, although a few studies have shown that, compared to conventional CABG with CPB, OPCAB is associated with a reduced incidence of NCD,^{64,67,68} most studies have shown no significant difference.^{31,69-71}

This failure of OPCAB to favorably impact postoperative NCD has been largely attributed to the partial-occluding aortic clamp and to microemboli liberated during its application and removal. Although OPCAB obviates the need to place a perfusion catheter for CPB or a cross-clamp for cardiac arrest, the side-biting partial-occlusion clamp, routinely used at many centers during construction of proximal anastomoses, arguably is equally traumatic.⁷² Avoidance of aortic manipulation by using composite grafts arising from the in situ LIMA and OPCAB has been shown to be an important factor in avoiding postoperative stroke.^{73,74} A number of new devices recently introduced into clinical practice (see earlier) allow proximal anastomoses to be constructed off-pump without application of a partial-occlusion clamp

(see Fig. 89-11). The impact these devices will have on NCD after OPCAB is yet to be determined.

LIMITED-ACCESS CORONARY ARTERY BYPASS

Additional efforts to minimize the invasiveness of CABG have focused on decreasing the trauma of surgical access. Although a median sternotomy is relatively well tolerated, patients must refrain from heavy lifting for 2 to 3 months to allow reunion of the sternum. The incidence of wound complications is low, but sternal wound infections can be life-threatening and generally require repeat operation. Moreover, the musculoskeletal trauma involved in spreading the sternal halves is associated with a small degree of systemic inflammatory response that is synergistic with CPB in causing morbidity.^{75,76} Avoiding a sternotomy is, therefore, an attractive idea.

Minimally Invasive Direct Coronary Artery Bypass (MIDCAB)

In 1995, Benetti and coworkers introduced the MIDCAB procedure,⁷⁷ which was rapidly adopted by multiple centers in the United States and Europe.^{78,79} The procedure is performed through a 7-cm anterior lateral thoracotomy, usually in the fifth intercostal space, and generally consists of a single-vessel off-pump procedure using the LIMA to bypass the LAD. Many early series yielded satisfactory results, including a substantially shorter

length of stay than for standard CABG, as well as decreased resource utilization, a reduced requirement for transfusion, and excellent graft patency.⁷⁸⁻⁸¹ Other reports suggested a reduced incidence of postoperative atrial fibrillation,⁸² but this finding has been refuted.^{14,83} Despite initial enthusiasm, traditional MIDCAB with LIMA harvest under direct vision is currently performed in large numbers in only a few U.S. centers. This decreased utilization is due in part to the technical hurdles involved in harvesting the LIMA under direct visualization through a small anterior lateral thoracotomy.

Several early reports documented successful results with endoscopic LIMA harvest.^{84,85} At many U.S. centers, however, surgeons chose to mobilize the LIMA by using direct visualization through a small thoracotomy to avoid the learning curve associated with videoscopic instrumentation and visualization. Direct harvest is often technically demanding and occasionally results in a LIMA graft of inadequate length. In addition, the vigorous chest-wall retraction required for LIMA exposure results in significant early postoperative pain. Nevertheless, several groups skilled in MIDCAB continue to perform the procedure in large numbers and report excellent results.^{81,86,87}

Hybrid MIDCAB Approach

Several reports have documented the successful application of a hybrid strategy in which a LIMA-to-LAD bypass (MIDCAB) is combined with catheter-based interventions on the circumflex artery and RCA for treating multivessel disease. In one multicenter series, videoscopic mobilization of the LIMA was performed with the aid of a voice-actuated robotic arm used to manipulate the scope (Fig. 89-12).⁸⁸ In this series, the pericardium was opened by using videoscopic techniques before the thoracotomy was performed. In many patients, this facilitated accurate placement of the chest-wall incision, allowing the anastomosis between the LIMA and LAD to be constructed without a rib spreader; only soft tissue

FIGURE 89-12 ■ Videoscopic mobilization of the left internal mammary artery may have a role in the continued evolution of less invasive CABG.

retractors and a specially designed bed-mounted stabilizer were used to expose the anastomotic site through the natural intercostal space (Fig. 89-13).⁸⁹ This approach significantly reduced postoperative pain. This experience generated resurgent interest in the MIDCAB procedure at many centers.

Completely Endoscopic Robotic-Assisted CABG

The literature describes a growing number of series involving completely closed-chest videoscopic LIMA-to-LAD procedures using surgical robots to mobilize the LIMA and to perform the sutured anastomosis, both with CPB^{90,91} and without CPB.^{90,92,93} The robots allow the surgeon to manipulate fully articulating videoscopic instruments by way of master-slave servos and microprocessor control. These instruments allow multiple degrees of freedom and can precisely emulate the surgeon's movements. An easy-to-use control environment, high-resolution displays that provide realistic three-dimensional stereopsis, and high magnification, as well as tremor filtering and motion-scaling options, offer the potential for superhuman precision. This precision compensates somewhat for the absence of tactile feedback. Although the concept is extremely exciting, the routine use of surgical robotics in CABG surgery does not seem imminent. The robots are expensive, and the learning curve for robotic totally endoscopic CABG (TECAB), especially if performed without CPB, is challenging. Surgeons skilled in the procedure can successfully perform only approximately one in three off-pump TECABs in carefully selected patients, resorting to a small MIDCAB incision to perform the anastomosis in the remainder. Future refinements in surgical robotic tools and techniques,

FIGURE 89-13 ■ In one type of less invasive bypass, accurate placement of the chest wall incision often allows the anastomosis between the left internal mammary artery and the left anterior descending artery to be constructed through the natural interspace without placement of a rib spreader.

improvements in automated distal anastomotic devices, and other advances may help determine the ultimate utility of robotics in CABG procedures.

Port-Access CABG

In 1996, Heartport introduced port-access cardiac surgery as a means of decreasing the trauma of surgical access. This strategy uses specialized catheters that are inserted into the femoral artery and vein and allow institution of CPB, balloon endoclamping of the ascending aorta, administration of antegrade cardioplegia, and venting of the ascending aorta. Additional catheters introduced percutaneously into the left jugular vein allow delivery of retrograde cardioplegia into the coronary sinus and venting of the pulmonary artery. A small chest incision can then be tailored for the desired procedure. In the late 1990s, several series of multivessel CABG operations performed through small fifth-intercostal-space thoracotomies were published that showed acceptable results from use of port access for institution of CPB,⁹⁴⁻⁹⁶ but this procedure is not widely used. Decreased enthusiasm is partly due to challenges associated with graft length and lie. Nevertheless, port access has remained an essential component of TECAB in several small series, and it remains an enabling technique in limited-access mitral procedures and atrial-septal defect repair. Advances in surgical robotics and automated distal anastomosis may have an impact on the ultimate role of port-access technology in the evolution of limited-access CABG.

TRANSMYOCARDIAL LASER REVASCULARIZATION

Transmyocardial revascularization (TMR) is an alternative surgical therapy for the treatment of severe coronary artery disease. Currently reserved for patients refractory to medical management, TMR is indicated when complete revascularization cannot be achieved with conventional percutaneous or surgical techniques. In an open TMR procedure, revascularization is achieved with a hand-held laser device that delivers thermal energy to the ventricle, creating 1-mm channels through vaporized myocardium with the aim to improve blood flow.

The efficacy of TMR in relieving symptoms of angina is well documented, and this procedure is no longer considered experimental.^{97,98} Initial positive results led to the approval of TMR by the Food and Drug Administration in 1998, and at least 20,000 procedures, in isolation or combined with CABG, have been performed in the United States.⁹⁹ To date, there remains a lack of long-term, randomized clinical data showing the superiority of isolated TMR over its use as an adjunctive therapy. Indications and long-term benefits remain in question, but ongoing investigations are helping to clarify the ideal use of this technology.

Operative Procedure

Open TMR is performed under general anesthesia and involves the direct application of laser energy to the

epicardial surface of the heart. Preoperative preparation includes chest roentgenography, echocardiography, and a nuclear perfusion scan or dobutamine stress echocardiogram to document hibernating myocardium, as scar tissue does not benefit from TMR.

All patients require intraoperative monitoring with continuous electrocardiography, a Swan-Ganz catheter, an arterial pressure line, and transesophageal echocardiography. A double-lumen endotracheal tube is used to isolate the left lung; this facilitates the procedure in patients who have had previous cardiac surgery and may have pleural or mediastinal adhesions. Skin preparation includes the groin, in case the need arises for IABP insertion. CPB and systemic anticoagulation are not required.

In isolation, TMR can be performed through a left anterior thoracotomy in the fifth intercostal space. After a retractor has been inserted to separate the ribs, the pericardium is opened and the epicardial surface of the heart exposed, with care to avoid previous bypass grafts. Starting near the cardiac base, channels are created in approximately 1-cm increments in a linear fashion, working inferiorly and moving superiorly toward the anterior surface of the heart. This technique prevents expected mild TMR-related bleeding from obstructing the progression of the operation. The number of channels created depends on the size of the ischemic area and of the heart itself. Care must be taken to avoid thinned and dilated myocardium.

TMR is performed with a carbon dioxide (CO₂) or a holmium:yttrium-argon-garnet (Ho:YAG) laser. Both types of lasers rely on thermal energy. The CO₂ laser beam is transmitted through a series of mirrors and lenses, whereas the Ho:YAG laser relies on an optical fiber. The CO₂ device delivers up to 1000 watts of energy, creating 1-mm channels with a 20- to 30-J pulse. By synchronizing the firing of the CO₂ laser with the R wave on the electrocardiogram, one can potentially avoid ventricular arrhythmias. A transmural channel is created by a single 40-msec pulse, which is confirmed on transesophageal echocardiography by the appearance of characteristic changes caused by laser energy dissipating into the blood within the ventricle.

The Ho:YAG laser differs in its method of creating transmyocardial channels. An optical fiber must physically puncture the epicardium before the laser is deployed. The Ho:YAG laser requires 20 to 30 pulses at 2 J to create a single channel, and the pulses are not synchronized to the electrocardiogram, so the arrhythmogenic potential is greater than with the CO₂ laser. The optical fiber must be manually advanced, and successful creation of a transmural channel does not require transesophageal echocardiographic confirmation. After completion of TMR, a chest tube is inserted and the thoracotomy closed. The patient is transferred to the intensive care unit for monitoring.

Clinical Results

Since the first clinical use of open TMR by Mirhoseini and colleagues¹⁰⁰ in 1983, subsequent data have consistently shown a clear and substantial reduction in angina pectoris.¹⁰¹ In multicenter studies comparing TMR to

optimal medical therapy, most TMR patients had at least a two-class reduction in their Canadian Heart Association angina status. Long-term follow-up data have confirmed the persistent relief of symptoms, as well as a possible increase in survival.¹⁰²⁻¹⁰⁴ Combined with CABG in selected patients who have limited options for revascularization therapies, TMR may improve long-term symptomatic relief and does not appear to increase the risk of procedure-related adverse events.^{103,105} TMR has also been used as an adjunct to stem cell therapy, and initial data have been encouraging.^{106,107}

Mechanism

The mechanism by which TMR provides symptomatic relief remains unclear, but three potential contributing effects are recognized: direct perfusion through the channels created by TMR; inflammatory effects resulting in angiogenesis; and sympathetic denervation. Originally, TMR was presumed to provide its benefit via perfusion of the created channels, ultimately affecting nearby capillaries within the myocardium. However, inconsistent reports documenting the long-term patency of these channels have given rise to substantial debate.¹⁰⁸⁻¹¹² Although some positron emission tomography/computed tomography studies have shown evidence of sympathetic denervation,¹¹³ it is difficult to isolate afferent sympathetic nerve fibers, and this mechanism of benefit remains theoretical. Moreover, neovascularization of the myocardium as a nonspecific response to myocardial injury has been demonstrated in previous studies, which have shown upregulation of molecular factors of angiogenesis, such as vascular endothelial growth factor, platelet-derived endothelial growth factor, and fibroblast growth factor.¹¹⁴⁻¹¹⁶ Ongoing research will ultimately help define the role of TMR in clinical practice; meanwhile, this procedure remains a useful tool in the cardiac surgeon's armamentarium.

CONCLUSION

Advances in surgical tools and techniques have given rise to a number of new options in the surgical management of coronary artery disease. Although additional data may be required before the relative merits of these options can be characterized, it is clear that this flexibility will better allow the surgeon to tailor the operative approach to fit the patient. This is especially important given the increased age and comorbidity of patients referred for coronary bypass.

Current State of Hybrid Revascularization and Recent Information

ROBOTIC AND ALTERNATIVE APPROACHES TO CORONARY ARTERY BYPASS GRAFTING

The standard approach for coronary artery bypass grafting (CABG) is median sternotomy using cardiopulmonary bypass. However, less invasive approaches, including off-pump CABG and smaller access surgeries with or without robotic assistance, have been developed. This chapter describes less invasive methods of coronary revascularization along with their associated outcomes, with emphasis on robotic CABG. Hybrid coronary revascularization techniques are also considered.

MINIMALLY INVASIVE SURGICAL CORONARY REVASCULARIZATION

Many alternatives to surgical coronary revascularization have been developed in the form of modifications to conventional CABG. These alternatives come under the broad rubric *minimally invasive coronary revascularization*.

It should be noted that when used in the realm of cardiac surgery, this description “minimally invasive” carries more possible meanings than in other surgical specialties. In contrast to other surgical disciplines where the degree of invasiveness of a procedure is primarily defined by the size of access incisions, in cardiac surgery

at least two forms of invasion can be altered. The trauma of physical access can be changed by the use of smaller incisions that involve less (or no) sternal splitting. The physiologic invasiveness can be altered by performing procedures off pump, that is, without the use of cardiopulmonary bypass and cardioplegic arrest. This at least theoretically modifies the degree of physiologic perturbation produced in performing the intervention.

The face of surgical coronary revascularization has been changed by innovations in both of these areas and inventions like the octopus stabilizer, spreaders for mini-thoracotomy approaches, devices for local coronary artery occlusion and shunting, the CO₂ mister-blower, long-shafted thorascopic instrumentation, robotic devices, and minimally invasive extracorporeal circulation have led to a completely different appearance of coronary surgery. Because off-pump coronary artery bypass (OPCAB) grafting is covered in [Chapter 89](#), it will not be covered in depth here; rather, this chapter describes techniques of surgical revascularization using access incisions other than conventional median sternotomy, with or without the use of cardiopulmonary bypass. The degree of revascularization possible with each intervention is discussed as well as some of the literature on the clinical outcomes associated with these approaches, with emphasis on robotically assisted approaches.

Minimally Invasive Direct Coronary Bypass

A minimally invasive direct coronary bypass (MIDCAB) operation (also referred to as single-vessel small thoracotomy direct-vision bypass grafting [SVST]) is a procedure using an anterior, medially placed, mini-thoracotomy incision. The incision is used for both direct-vision left internal mammary artery (LIMA) harvest and creation of an anastomosis of the LIMA to a coronary artery.¹ It is performed off pump and requires the use of a stabilizer placed either directly through the operative incision or through a separate port incision.

Because of the limited access to the lateral and posterior surfaces of the beating heart during this procedure, coronary revascularization using MIDCAB is generally limited to the bypass of the left anterior descending (LAD) artery or its diagonal branches. To allow for takedown of the internal mammary artery (IMA) through this incision, specially designed retractors are available. (In the early development of MIDCAB, rib disarticulation or removal of cartilage was carried out.) The MIDCAB, therefore, essentially amounts to a one-vessel OPCAB to the LAD or its diagonal branches through a small thoracotomy.

Having originally been described in 1965 by Kolessov, the MIDCAB procedure was reintroduced in the mid-1990s. The procedure was adopted at many U.S. and European centers after its reintroduction, and many early series demonstrated decreased hospital lengths of stay relative to conventional CABG, decreased utilization of resources, earlier return to full activity, reduced transfusion requirement, and excellent graft patency.² When compared to a single-vessel OPCAB, data are limited;

however, small studies suggested that durations of mechanical ventilation and total hospital stay were decreased with use of MIDCAB.³

The main downside of this procedure is challenging early postoperative control of pain caused by the chest wall retraction involved in LIMA harvest.¹ Even with the smaller incision, the difficulties with postoperative pain may have contributed to the decrease in popularity of this procedure after its original introduction. Nevertheless, several centers skilled in this approach continue to perform it in large numbers and report excellent results.

For example, in one recent European report, Holzhey and coworkers reported their experience with 1768 MIDCABs between 1996 and 2009.⁴ This Leipzig group reported a 1.75% rate of conversion to sternotomy, 0.8% postoperative mortality rate, and 0.4% perioperative stroke rate. Routine postoperative angiograms showed 95.5% early graft patency, with a short-term target vessel reintervention rate of 3.3%. MIDCAB procedures have also been used successfully in the reoperative arena⁵ with some evidence of decreased operative mortality. The general acceptance of MIDCAB is low, and despite initial enthusiasm, several centers have abandoned the procedure. The significant learning curve for an individual surgeon to reach stable results (additionally requiring continuously high case loads to sustain surgeon skill^{4,6}) and less than optimal graft patency at some centers are probably the main causes for this phenomenon.

Preoperative Considerations

All patients should undergo the complete preoperative workup that is standard for open CABG. The patient's body mass index and body habitus are of worthy of note; obesity is a relative contraindication for MIDCAB because the pressure placed on the wound edges by the retractor during LIMA takedown may cause tissue necrosis and predispose the patient to wound infection. For similar reasons, female patients with large breasts may be at increased risk for wound-related complications.⁷ With regard to preoperative imaging, preoperative assessment of heart position relative to the interspaces on chest x-ray may be helpful in the planning of the access incision.

Technical Details

The patient is positioned supine with the left side up. Optimally single-lung ventilation is used; however, this is not absolutely necessary. If single-lung ventilation is not used, reduction in tidal volume and packing of the lung away from the field can be used. A left submammary incision in the mid-clavicular line in either the fourth or fifth interspace is used^{8,9} ([Fig. 90-1](#)). Review of the heart position relative to the interspaces on preoperative chest x-ray can be helpful in the planning of the access incision. It should be noted that the incision is the lower limit of LIMA takedown; the chest wall caudal to the incision cannot be visualized. Therefore, some physicians preferentially take the fourth interspace approach to obtain maximal conduit length.⁸ This consideration is important in the case of a distal LAD lesion. Some reports have described extensions of the LIMA by a segment of an

FIGURE 90-1 ■ The limited left anterolateral thoracotomy for minimally invasive direct coronary artery bypass (MIDCAB) is approximately 5 to 7 cm, commencing in the midclavicular line in the fourth intercostal space. Also shown is the port placement for the endostabilizer, which can be used later for insertion of a chest tube. (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2014. All rights reserved.)

additional arterial conduit to reach distal LAD targets and to avoid graft tensions.¹⁰

Following incision, a chest wall retractor is inserted for LIMA takedown. In general, retractors used for this purpose (e.g., those made by Medtronic, Inc., Minneapolis, MN) have an elongated superior blade designed to retract the upper ribs away, preventing their acting as a shelf limiting visualization (Fig. 90-2). The pleural fat is dissected away, the endothoracic fascia is exposed and incised with bovie electrocautery, and the LIMA is taken down in skeletonized fashion. It is recommended to locate the LIMA medial to the incision and proceed cephalad to the level of the subclavian vein.⁸ After heparin reaches activated clotting time (ACT) levels of 300 sec, the artery is divided at its distal extreme

FIGURE 90-3 ■ Endostabilizer has been inserted and left anterior descending artery is exposed for grafting. Note the presence of a soft tissue retractor to optimize visibility. (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2014. All rights reserved.)

and the LIMA retractor is replaced with a standard thoracotomy retractor.

The pericardial fat pad is then removed. The phrenic nerve should be identified and the pericardium incised longitudinally anterior to it to the level of the base of the heart. The apex is identified and the LAD in its position to the right of the apex coursing parallel to the sternum. Care must be taken not to misidentify the diagonal artery as the LAD, which may be the first artery visualized. In contrast to the LAD, the diagonal artery courses parallel to the incision and toward the apex.⁷ Pericardial stay sutures may be useful in positioning the heart.

Once the LAD has been identified, it is stabilized either directly via the incision or using an endostabilizer brought through a separate lateral stab incision (Fig. 90-3). If the latter is used, this incision can also be used later for chest tube placement. Silastic loops are placed proximally and distally if necessary (note that distal snares should be avoided because they can lead to scar lesions and impaired flow), and the artery is exposed. Premedication with lidocaine or other antiarrhythmic can be used before vessel occlusion. Should hemodynamic compromise be encountered following occlusion, a 1.5-mm intracoronary shunt can be used, with the vessel occluders released, while the anastomosis is created. Whether shunted or not, anastomosis creation is performed in the standard fashion with 7-0 Prolene. It is recommended to assess flow with transit time ultrasound.

After heparin reversal and confirmation of hemostasis, the pericardium is loosely reapproximated to prevent heart herniation and adherence of the apex to the intercostal space. Some authors recommend reapproximation using a patch of bovine pericardium for this purpose.⁷ It is important to take care to avoid kinking of the LIMA, particularly as it passes through the pericardium during this process. A nerve block may be achieved by direct infiltration of 0.5% bupivacaine into the posterior intercostal spaces from ribs four to six. A single chest tube is placed in the left chest, the ribs are reapproximated, the pectoral muscle is reapproximated, and the skin is closed in standard fashion.

Postoperative Considerations

Patients can be extubated on the table; however, if patients are left intubated, any double-lumen endotracheal tubes inserted should be exchanged for single-lumen tubes. Aggressive pain management and a strategy of early mobilization should be instituted. If necessary, a thoracic epidural catheter may be used if less invasive pain control methods (narcotics, Lidoderm topical patches, etc.) are not sufficient.⁷ No sternal precautions are required following MIDCAB.

It is recommended to begin aspirin and clopidogrel 6 hours after surgery or once chest tube drainage is minimal⁷; there is some evidence that the use of dual antiplatelet therapy reduces the risk of perioperative myocardial infarction and graft occlusion in off-pump revascularization procedures.¹¹

Thoracoscopic MIDCAB

In an effort to avoid the degree of chest retraction typically involved in the standard MIDCAB procedure, other approaches to LIMA takedown have been developed. In the video-assisted MIDCAB approach (also referred to as “endo-ACAB”), the LIMA is harvested thoracoscopically via small access port incisions. The LIMA-LAD anastomosis is created through a mini-thoracotomy with minimal rib spreading. It should be noted that thoracoscopic LIMA takedown requires chest cavity insufflation, and patients’ ability to tolerate diminished ventilation intraoperatively should be assessed preoperatively.¹

The largest series of thoracoscopic MIDCAB was reported by Vassiliades and colleagues in 2007 who termed this approach *endoscopic atraumatic coronary artery bypass* (endo-ACAB). This group reports a 3.6% conversion to sternotomy or thoracotomy rate, a 1% postoperative mortality rate (to be compared to the STS National Database–predicted 30-day mortality of 2.7%), and a 0.3% stroke rate. These authors report a 96% LIMA-LAD patency rate with a mean follow-up of 18 months. The mean length of stay in the intensive care unit was 11.2 ± 9.9 hours, and in the hospital, 2.4 ± 1.3 days.¹²

Likely because of the advanced thoracoscopic skills necessary for the LIMA takedown in this approach (with an estimated 50-case learning curve required for mastery of the technique¹³), the thoracoscopic MIDCAB has not achieved widespread adoption at this time. However, centers with expertise in the technique have obtained promising results. Robotically assisted MIDCAB represents an alternative to thoracoscopic MIDCAB and is discussed in conjunction with other robotic revascularization techniques later.

Preoperative Considerations

All patients should undergo the complete preoperative workup that is standard for open CABG. The patient’s body mass index and body habitus are worthy of note, as in open MIDCAB. In general, patients with body mass index less than 30 are the most straightforward for those surgeons early in their learning curve. Women with large

breasts can be challenging because port sites may need to pass through the breast itself, or a larger submammary incision may be required. Preoperative spirometry may be helpful in determining the patient’s ability to tolerate the single-lung ventilation (with forced expiratory volume in 1 second [FEV₁] < 1 usually representing the cutoff value).¹⁴

Technical Details

As in an open MIDCAB, the patient is positioned supine on the operating room table with the left side up.

Under single-lung ventilation, three ports are placed in the left midaxillary line in the third, fifth, and seventh interspaces (some physicians recommend the fifth interspace port be placed in the anterior axillary line¹⁵). Standard thoracoscopic instruments can be used. A 30-degree (either 5-mm or 10-mm) thoracoscope is inserted via the fifth space first, and carbon dioxide insufflation is initiated to a target pressure of 8 mm Hg to increase the workspace inside the chest. It should be noted that if hemodynamic compromise is observed (a result of hypertensive pneumothorax, especially in patients with compromised left ventricular function) at this stage, it may be necessary to decrease the rate of insufflation or to evacuate some of the carbon dioxide from the thoracic space. The endoscope should then be inserted and a general view of the intrathoracic space obtained.

Next, a grasper and electrocautery or harmonic scalpel are inserted through the third and seventh interspaces. Following dissection of pleural fat, the endothoracic fascia is visualized. The fascia should be incised approximately 1 cm lateral to the IMA and retracted downward. Using gentle spatulation with the electrocautery or harmonic scalpel to identify the side branches of the IMA, the entire IMA can be harvested from the subclavian vein to the level of the xiphoid process through the cautery or harmonic division of its branches (clips are seldom used) in pedicled fashion.^{7,15} Care should be taken at the level of the first rib to avoid damage to the phrenic nerve and subclavian vein.

The pericardium may be opened and the target vessel identified. Anastomosis creation proceeds in a manner similar to that described for open MIDCAB, with incision placement guided by the thoracoscope. One of the port sites may be used for endostabilizer placement and subsequently the chest tube.

Postoperative Considerations

As in open MIDCAB, patients may be extubated on the table; however, if patients are left intubated, double-lumen endotracheal tubes should be exchanged for single-lumen tubes. Aggressive pain management and a strategy of early mobilization should be instituted. No sternal precautions are necessary. It is recommended to begin aspirin and clopidogrel 6 hours after surgery or once chest tube drainage is in keeping with the evidence that the use of dual antiplatelet therapy reduces the risk of perioperative myocardial infarction and graft occlusion in off-pump revascularization procedures.¹⁶

MULTIVESSEL MINIMALLY INVASIVE PROCEDURES

As described earlier, MIDCABs are generally restricted to the performance of a single LIMA-LAD or LIMA-diagonal bypass. The benefits of this method can be expanded to those patients with multivessel disease by combining MIDCAB with percutaneous coronary intervention (PCI) for lesions on the posterior and lateral surfaces of the heart in a hybrid approach. This hybrid method, however, can be used only when such lesions are amenable to PCI. This has led some physicians to create other minimally invasive alternatives for patients with multivessel disease.

The use of bilateral MIDCABs involving the use of bilateral anterior (medially placed) mini-thoracotomy in conjunction with bilateral direct-vision internal mammary as well as radial artery conduits has been reported¹⁷ but not been evaluated in large studies. The use of bilateral thoracoscopic IMA harvesting followed by right anterior thoracotomy for the bypass of right coronary artery and LAD territories has also been described. It should be noted, however, that in using this technique, bilateral thoracotomies were required to reach posterolateral vessels and it was not possible for the posterior interventricular branch to be bypassed.¹⁸

Techniques involving a single thoracotomy for multivessel disease have also been developed. One procedure, termed the *anterolateral thoracotomy–coronary artery bypass* (ALT-CAB) uses larger left thoracotomy. Through this incision, both the LIMA and the right internal mammary artery (RIMA) can be harvested under direct vision and the greater access to the heart allows all territories to be bypassed. Additionally, central cannulation is possible because of the greater exposure afforded by the larger incision. The procedure has not achieved widespread adoption, but it has been used in selected centers with acceptable results. In a series of 255 patients undergoing this procedure, complete revascularization was achieved in all patients and there were no conversions to cardiopulmonary bypass. The mortality and stroke rates in this series were 1.2% and 0.8%, respectively, with 65.1% of patients discharged within 48 hours of ALT-CAB.¹⁹

The newest non-robotic minimally invasive option for treating multivessel disease, introduced in 2005, is termed *minimally invasive cardiac surgery/coronary artery bypass grafting* (MICS CABG)¹⁸ (sometimes referred to as multivessel small thoracotomy [MVST]).²⁰ This approach uses a more laterally placed thoracotomy than a traditional MIDCAB. A specialized pivoting retractor allows for a full-length LIMA takedown through the thoracotomy, and two port-site incisions allow for the use of an epicardial stabilizer and an apical positioner. As a result of the position of the access incision along with the ability to position the heart with the apical positioner and epicardial stabilizer, all territories of the heart can be bypassed with this technique. The procedure is performed off pump and does not require the use of thoracoscopic or robotic equipment; it essentially amounts to a multivessel OPCAB performed through small incisions.

It should be noted that a limitation of MICS CABG is that right IMA takedown is not possible without use of a larger incision, thoracoscope, or robotic assistance.²¹ However, this limitation may be offset by the use of saphenous vein grafts with proximal anastomoses to the ascending aorta, a technique that has been practiced in selected centers.¹⁸

A dual center series of 450 patients over 3.5 years was reported for the MICS CABG and showed encouraging results. The authors report a 1.3% mortality rate and a 0.4% stroke rate. Complete revascularization was reported in 95% of patients undergoing this technique. No angiographic evidence with respect to graft patency was reported; however, at 19-month mean follow-up, 3% of patients required PCI. A 3.8% conversion to sternotomy was reported, and conversion to on-pump procedure (via peripheral cannulation) was reported in 7.6% of cases. It is interesting to note that the initial report included the entire experience of the institutions with the procedure, including their initial experiences. The authors suggest that this implies that this procedure may be implemented and developed without the occurrence of a significant learning curve with respect to morbidity and mortality. Proponents of this procedure assert that it has a greater availability for all cardiothoracic surgeons because the procedure does not require the costly infrastructure and disposable materials associated with robotic or thoracoscopic procedures.²⁰

Recently, MICS CABG was compared in case-matched fashion to standard OPCAB in a single surgeon's practice. Each group contained 150 patients and was matched with respect to age, gender, left ventricular function, and median number of distal anastomoses. The authors found significantly decreased length of stay (5.4 days vs. 7.2 days OPCAB, $P = 0.02$), wound infection (0 vs. 4% OPCAB, $P = 0.002$), and median time to return to full activity (12 days vs. >5 weeks OPCAB, $P < 0.001$) in favor of MICS CABG over OPCAB. There were no differences in mortality rate or rate of atrial fibrillation between groups, but there was a higher rate of pleural effusion in the MICS CABG group (15% vs. 4%, $P = 0.002$).²² No long-term data on graft patency are available, but early studies suggest excellent short-term patency rate (92% for all grafts, 100% for LIMA grafts at 6 months).²³ Additional data are needed to more fully evaluate this procedure, but it may have potential as a more widely adoptable minimally invasive surgical option for patients with multivessel disease.

Robotically Assisted Revascularization

Robotic surgical systems are telemanipulators in which a surgeon controls micro-instruments remotely from a console. The most widely used system is the da Vinci Si (Intuitive Surgical, Mountain View, CA). The system conveys high-definition three-dimensional imaging to the surgeon at the console and sensors register finger and wrist movements and translate them (tremor-free) into the motion of the micro-instruments in the operative field. The da Vinci robot was approved for cardiac surgery in 2002. Approximately 2000 robotic cardiac operations are performed in the United States per year, most of

which take place in a small number of experienced centers. The number of procedures is increasing modestly but represents a small fraction of the total number of cardiac surgical interventions performed yearly.²⁴

The use of robotics in minimally invasive cardiac surgery was intended to overcome some of the limitations of thoracoscopy. For example, thoracoscopic instruments offer only four degrees of freedom, a level not adequate for the delicacy required by cardiac surgery. The long shafted instruments may be prone to fulcrum effects and shear forces may be exerted at port sites, contributing to postoperative pain from intercostal nerve trauma. In addition, the surgical field images in thoracic surgical systems are presently two-dimensional; this loss of depth perception can impair surgical performance in delicate situations.²⁵

Surgical robotic systems are used in coronary revascularization in various ways, from robotically assisted MIDCAB (robotic IMA harvest with hand-sewn anastomosis using anterior thoracotomy or sternotomy) to totally intrathoracic revascularization (IMA takedown and bypass creation) performed solely through small port site incisions (totally endoscopic coronary artery bypass [TECAB]). TECAB can be performed with or without use of cardiopulmonary bypass and cardioplegic arrest. When cardioplegic arrest is used, the term *arrested heart TECAB* (AH-TECAB) is used. When the heart is not arrested, the procedure is referred to as *beating heart TECAB* (BH-TECAB).

The earliest use of robotic technology (late 1990s to early 2000s) in coronary revascularization recapitulated the role of thoracoscopy in the thoroscopically assisted MIDCAB, described earlier. Namely, robotically assisted IMA harvest was performed followed by single hand-sewn anterior anastomosis through a small thoracotomy in an off-pump fashion. When compared with a single-vessel OPCAB, robotically assisted MIDCAB has been associated with a shorter hospital stay and quicker return to work.²⁶ As with thoroscopically assisted MIDCABs, robotically assisted MIDCABs have also been described as key components of hybrid revascularizations, which are described later.

TECAB may be used for single- or multiple-vessel bypasses (generally using bilateral IMAs in multivessel cases) and represents the least physically invasive means of coronary revascularization. In contrast to other minimally invasive approaches, TECAB does not involve the use of incisions larger than port sites. Both on-pump and off-pump TECABs have been described. First performed in 1998,^{26a} TECAB has been described by proponents as having advantages of minimal surgical trauma and rapid recovery. Scarring is reduced compared with mini-thoracotomy approaches and no rib spreading is involved, resulting in minimal intercostal nerve trauma and less postoperative pain. Series from the early 2000s showed short hospital stays, early return of patients to full activities following TECAB, and rare deep thoracic wound infections, as a result of the minimal exposure of the operative field to the ambient environment. It has been suggested that the obese may benefit more from TECAB with respect to wound complications, as the operative exposure is no different in obese versus non-obese patients using this approach.²⁷

A recent review²⁸ of published series on TECAB found rates of 0.4% all-cause mortality, 0.8% perioperative stroke, 1.8% myocardial infarction, 5.1% new onset atrial fibrillation, 1.2% renal failure, 2.3% early reintervention, and 5.8% revision for bleeding in 360 AH-TECABs. These results compare favorably with conventional approaches with the exception of reoperation for bleeding. The early patency rate was 96.4% (in the 253 patients who had some form of early imaging study). Data on intermediate and long-term follow-up are scarcer in the literature. However, at 5-year follow-up on 62 one-vessel disease patients undergoing TECAB, a survival rate of 95.8%, freedom from MACCE rate of 83.1%, and freedom from angina rate of 91.1% have been reported.²⁹ The longest-term follow-up on graft patency available comes from Currie and colleagues¹⁶ who at 8-year follow-up (using coronary angiography, CTA, and stress myocardial perfusion scintigraphy) found a 92.7% overall patency rate in a mixed on-pump and off-pump population consisting of 82 patients.

Technical Details

Preoperative Evaluation

All patients should undergo the complete preoperative workup that is standard for open CABG. We also recommend that every patient undergo a preoperative CT angiography of chest, abdomen, and pelvis. This allows the surgeon to assess for the size of the heart and its relation to the chest wall, size of the pericardial fat pad, and relation of the IMAs to the target vessels. In our experience, a distance of less than 25 mm from the left heart border to the chest wall can lead to significant technical challenges because of insufficient working space. In addition, the courses (intramyocardial vs. epicardial) of the target vessels should be determined along with the ascending aortic diameter and grade of aortoiliac atherosclerosis. We also recommend spirometry in all patients being considered for TECAB. These values are important not only for determining the patient's ability to tolerate single-lung ventilation during IMA takedown but also for gaining a sense of intrathoracic volume. We have observed an FEV₁ of less than 2.5 liters to be an important cutoff value; under this level, intraoperative technical difficulties (related to space limitations) and postoperative morbidity increase.

The Role of Cardiopulmonary Bypass and Cardioplegic Arrest in TECAB

As mentioned earlier, TECAB can be performed with or without the use of cardiopulmonary bypass. Many patients benefit from beating heart approaches and, ideally, TECAB surgeons should become facile with BH-TECAB. Endoscopic suturing is technically more challenging than in the arrested heart approach, and surgeons are strongly advised to perform on-pump operations with endocardioplegia first. If a BH-TECAB is planned, we recommend prophylactic peripheral cannulation in all cases under all circumstances; the surgeon must be prepared for the worst case scenario of ventricular fibrillation with

the robot docked. Without prior cannulation and the ability to immediately initiate cardiopulmonary bypass, the situation can rapidly grow dire, with potential for great harm to the patient as well as to the TECAB program at the surgeon's institution. Therefore, we reiterate our recommendation to prophylactically cannulate all cases under controlled conditions with connection to the heart-lung machine tubing so that its immediate use can be used. Starting the pump and deflating both lungs can also allow the surgeon to gain significant additional space inside the chest if needed in a BH-TECAB. In some patients, this is the only way to develop adequate space and hemodynamics to access the back wall of the heart.

AH-TECAB requires specific perfusion and cardioplegia skills. Remote access cardiopulmonary bypass and the use of ascending aortic balloon occlusion are technically challenging and require discipline in patient selection. Femoral cannulation and endoballoon should be used only in patients without aortoiliac atherosclerosis (approximately two thirds of patients currently eligible for TECAB fall into this category). Axillary antegrade perfusion and femoral insertion of the endoballoon are the best option for patients with moderate grades of aortoiliac atherosclerosis. Transthoracic clamping and direct aortic root cannulation for cardioplegia are an option but in its early stage of development; challenges associated with this technique include transthoracic puncture of the ascending aorta, insertion of an appropriate catheter, and endoscopic robotic control of bleeding after catheter removal. Surgeons are advised to develop remote access perfusion techniques in other minimally invasive heart surgery before they apply them in TECAB. Introducing both robotic coronary surgery and advanced peripheral heart-lung machine techniques at the same time must be avoided.

With the previously mentioned safety measures in mind, we have found that both AH-TECAB and BH-TECAB are fascinating operations performed at a high level of comfort for the surgeons and their teams.

Technical Considerations in Cannulation

If there is no aortoiliac atherosclerosis on preoperative CT angiography, femorofemoral heart-lung machine perfusion and use of the endoaortic balloon are safe. The femoral vessels are exposed in the groin, usually on the left side. All cannulation maneuvers can be carried out while one team member performs robotic IMA harvest. Arterial and venous cannula placement is carried out under strict transesophageal echocardiography (TEE) guidance with the patient heparinized to an ACT of 300 sec, and additional heparin to an ACT of 480 sec is administered shortly before the initiation bypass. It is of great importance to ensure arterial distal leg perfusion, and we recommend insertion of a distal perfusion cannula into the superficial femoral artery in all cases. A 21 Fr or 23 Fr arterial perfusion cannula with a side arm for the endoballoon catheter is then inserted and connected to the heart-lung machine tubing. Similarly, a 25 Fr venous drainage cannula is brought up into the right atrium and superior vena cava and connected to the heart-lung machine tubing. The aortic endoballoon catheter is inserted into the side arm of the arterial perfusion cannula

and advanced into the aortic root over a guidewire. The catheter is connected to the cardioplegia-vent line of the heart-lung machine, and aortic root pressure and balloon pressure lines are connected to the monitoring devices. Once adequate ACT levels (>480 sec) are confirmed, the heart-lung machine is started slowly. It is important to ensure that adequate venous drainage has been achieved, a drop in systemic perfusion pressure is observed, and lack of ventricular ejection (balloon placement is easier in nonejection conditions) is observed. The surgeon then locates the endoballoon on an adequately visible TEE monitor, inflates the balloon, and immediately injects 6 mg of adenosine into the aortic root. Adenosine induces cardioplegia immediately; this is followed by infusion of antegrade cardioplegia into the aortic root. If a percutaneous retrograde cardioplegia catheter was placed into the coronary sinus, standard protocol of antegrade and retrograde cardioplegia infusion can be followed.

If mild to moderate aortoiliac atherosclerosis is present, we avoid arterial retroperfusion through the femoral artery and instead cannulate the left axillary and use a nonperfusing endoballoon. For anatomic access reasons this is best done before docking of the robotic arms. The vessel is exposed in the left infraclavicular region, clamped and incised after heparinization, and an 8-mm Dacron prosthesis side arm is sutured to the axillary artery. After proper de-airing, the side arm is connected to the heart-lung machine tubing. In these cases, the aortic endoballoon is inserted through a separate 19 Fr cannula in the femoral artery.

In the case that preoperative CT angiography shows significant aortoiliac and general atherosclerosis, forgo endoballoon use and operate on the beating heart with prophylactic peripheral cannulation. The axillary artery is exposed and cannulated as described earlier. The venous drainage cannula is inserted via the femoral vein in percutaneous or open fashion. An ACT level of 300 sec is again used for cannulation. Before starting the anastomosis on the beating heart, the ACT is increased to above 480 sec. Using this strategy, the pump can be started expeditiously at any time point should significant technical difficulties occur.

Procedural Details

Single-lung ventilation and TEE monitoring are mandatory throughout the entire procedure. R2 defibrillator patches are placed with care so that adequate current flow is facilitated and sternotomy can be allowed. An endovent and/or percutaneous retrograde cardioplegia cannula are placed if AH-TECAB is planned.

The patient is placed on the operating table in the supine position with arms tucked and left chest slightly elevated using a subscapular pillow or rolled towel (Fig. 90-4). The patient should be prepped and draped as for open coronary bypass surgery (CABG), with all equipment for conversion to open CABG available in the room.

Correct insertion of the endoscopy ports is a key to the procedure and significantly influences the success of the whole procedure; therefore, port insertion should be performed by the most experienced team member. After

FIGURE 90-4 ■ Operating room setup for totally endoscopic coronary artery bypass (TECAB). (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2014. All rights reserved.)

deflation of the left lung, a 12.5-mm camera port is used and inserted into the fifth intercostal space in the anterior axillary line. It should be inserted gently and cautiously so as to avoid injury to the heart or mediastinum. Once inserted, CO₂ insufflation at pressures of 8 mm Hg can begin and the angled camera can be inserted. The left and right instrument ports are then placed into the third and seventh intercostal spaces slightly anterior to the camera port under direct videoscopic vision. During this phase, the surgical team should remain aware of the patient's hemodynamics because the increase in intrathoracic pressure may cause hemodynamic compromise. Remaining in communication with the anesthesia team is critical; if hypotension develops during insufflation, the first attempts at correction should be to lower the CO₂ pressure or evacuate intrathoracic CO₂ (via one of the ports) rather than administer fluid or inotrope by anesthesia.

Following port placement, the robotic system is docked (see Fig. 90-4) and the IMA is harvested. This part of the procedure is done with the angled camera view in the up position. The robotic electrocautery spatula and a DeBakey forceps are inserted under videoscopic vision into the right and left ports, respectively. Using low power levels (we use 15 watts) on the electrocautery, the endothoracic fascia is detached from the IMA pedicle. The IMA is harvested in skeletonized fashion. In general, most side branches can be cauterized with clips used only for larger branches. The operator should use the cautery tip for dividing and dissecting the adjacent tissue mechanically, that is, by spatulation rather than tissue-burning maneuvers (Fig. 90-5). After harvesting and heparinization, the conduit is clipped distally, divided, and dropped

FIGURE 90-5 ■ Patient positioning for totally endoscopic coronary artery bypass (TECAB) with port placement sites. Ports are placed four fingerbreadths apart. (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2014. All rights reserved.)

into the left pleural space to allow autodilation to occur. It should be noted that both the left and the right IMA can be taken down using this technique with the same port and instrument arrangement. To access the right IMA, the retrosternal tissue is divided and the right pleura is entered. When bilateral conduits are used, the right IMA is harvested before the left IMA. Approximately midway through LIMA takedown, we fully heparinize the patient. In keeping with our recommendation for cannulation in all cases, this allows bypass to be started expeditiously at any time point should significant technical difficulties occur as the case proceeds.

A 5-mm assistance port is placed after IMA harvesting in the left parasternal region under scope visualization. This port allows insertion of material needed throughout the procedure such as bulldogs, suture material, Silastic tape, and suction tubing. In our experience, the TECAB procedure became smoother and faster with this trans-thoracic assistance.

Next, the pericardial fat pad is removed and pericardiectomy performed with the angled camera view down. To access the heart, the pericardial fat pad is mobilized using robotic long-tip forceps through the left port and electrocautery at 30 watts on the right and dropped into the left chest. The pericardium is then incised slightly lateral to the right ventricular outflow tract and extended all the way down to the reflection of the pericardium. The pericardial incision is then taken laterally in the caudal and cranial part so that a pericardial flap is created which falls into the left pleural space. Going on-pump before this phase facilitates this phase because both fat pad resection and pericardiectomy are significantly easier with an unloaded heart, especially in obese patients and those with cardiomegaly.

Exposure of Target Vessels

For all work on the coronary targets, the camera should continue to be in the down view position. The LAD can be visualized and accessed without difficulties using the port arrangement described earlier. In BH-TECAB and AH-TECAB cases with lateral target vessels, the LAD can be moved into an easily accessible position using the

robotic endostabilizer brought in through a subcostal port inserted two fingerbreadths left lateral to the xiphoid angle. This subcostal port is docked to the fourth arm of the robotic system.

The endostabilizer can be used for exposure of the circumflex coronary artery system. The operator should steer the endostabilizer gently over the left ventricle. The lateral wall can be lifted and the obtuse marginal branches accessed. In BH-TECAB, this maneuver can lead to hemodynamic compromise and ischemic changes. A supportive cardiopulmonary bypass run should be used to obviate this problem.

The right coronary artery system may also be accessed from the patient's left side. In this case, the endostabilizer is inserted through the left instrument port (change to a 12-mm port is necessary) and the left robotic instrument is inserted through the subcostal port. The acute margin can be lifted so that the posterior descending artery and the posterolateral branch are easily visible and accessible for anastomosis. It should be noted that thus far, this technique has been performed only on the arrested heart. It is important to take care not to injure the right ventricular epimyocardium with the endostabilizer during these maneuvers.

Once the target coronary artery is properly located and exposed, a robotic DeBakey forceps on the left and robotic Pott scissors on the right are used to incise the epicardium. At first, this can be challenging because of the lack of tactile feedback that is part and parcel to robotic work, and care must be used.

The target vessel is then incised using robotic DeBakey forceps on the left and robotic lancet beaver knife on the right, and the arteriotomy is extended with a robotic Pott's scissors (Fig. 90-6). The LIMA is prepared (Fig. 90-7). Bilateral robotic black diamond microforceps are used as needle drivers, and a 7-cm 7-0 double-armed polypropylene suture is used as suturing material. The first stitch is inside-out on the coronary artery, forming the first bite of the first stitch of the back wall of the anastomosis close to the toe. This needle is then "parked" at a distance from the anastomosis in the epicardium, and the anastomosis is continued with the other arm of the stitch, suturing the whole back wall going inside-out on the graft and outside-in on the target vessel (Fig. 90-8). The first three stitches are placed, and the graft is brought

toward the coronary artery wall in typical parachute technique. The operator pulls gently on both suture ends frequently to ensure adequate suture tension. Suturing then continues around the heel of the anastomosis, again suturing the graft inside-out and the target vessel in an outside-in fashion (Fig. 90-9). The needle is then parked in the epicardium and the previously used needle is used to suture the toe and rest of the anterior wall of the anastomosis (Fig. 90-10).

Points on Anastomotic Creation in Arrested Heart TECAB

The coronary artery should be incised with antegrade cardioplegia running to fill the vessel and reduce the risk of back wall injury. Use of Silastic vessel occluding loops can be very helpful in cases of target vessel backflow that prevents a clear view of the anastomotic interior. Gentle probing maneuvers at the toe and heel before completion of the anastomosis can be performed safely (Fig. 90-11). All foreign material should be removed from the chest before the aortic endoballoon is deflated. The heart can become hyperdynamic later, and these maneuvers will be difficult.

Points on Anastomotic Creation in Beating Heart TECAB

Vessel-occluding Silastic tapes should be placed both proximally and distally to the anastomotic site although

usually only the proximal one needs to be occluded. An intraluminal shunt is then inserted into the distal target vessel and advanced into the proximal target vessel. The general suturing pattern is the same as in AH-TECAB; however, all stitches have to be carried out with an extra degree of gentleness to avoid injury to the target vessel wall. The magnified bouncing operative field is challenging until experience has been gained by the surgeon.

Multivessel TECAB

Multivessel TECAB may be achieved using bilateral in situ mammary artery grafts, sequential grafting, or Y-grafts constructed with the contralateral IMA or radial artery. Use of an endoscopically harvested vein graft with proximal anastomosis creation to the left axillary artery has been described.³⁰

Post-Anastomosis Procedures

After completion of the anastomosis, the bulldog clamp on the graft is removed and the anastomosis is inspected. In the robotic setting with high magnification, repair sutures can be placed with excellent visualization if needed. The endostabilizer is removed from the chest and an endoscopic transit time flow probe is brought in for intraoperative flow measurements. Once adequate pump function without signs of myocardial ischemia is ensured, protamine is administered. A tracheal suction tube is brought in through the parasternal assistance port, and residual blood is evacuated from the pleural space. The thoracic cavity is thoroughly inspected and hemostasis is obtained. The robotic system is undocked but all ports are left in place, to be removed under direct video-scopic vision tableside. A chest tube is inserted through the camera porthole with the left lung inflated so as to avoid injuries to the graft during tube insertion.

Postoperative Considerations

Postoperative treatment after TECAB follows the general principles applied in open coronary bypass surgery. Some specifics, however, need to be taken into consideration. Currently no temporary pacing wires that can be placed endoscopically exist; other methods of temporary pacing (e.g., endovenous or transthoracic) are used if necessary. Special attention (neurovascular checks) should be paid to peripheral pulses following cannulation in AH-TECAB. Because of double-lumen tube intubation and single-lung ventilation, respiratory compromise can occur, and the postoperative chest x-ray may show increased rates of atelectasis compared with open surgery and is to be expected. The camera port site is usually the most painful site until the chest tube is removed, and additional pain control is necessary until that time. No sternal precautions are required. In the case of BH-TECAB, we recommend initiation of both aspirin and clopidogrel 6 hours following surgery (or once chest tube drainage is minimal), in keeping with the data suggesting that the use of dual antiplatelet therapy reduces the risk of perioperative myocardial infarction and graft occlusion in off-pump revascularization procedures.¹⁶

HYBRID CORONARY REVASCULARIZATION

Introduction and Definition

Hybrid coronary revascularization (HCR) combines surgical and catheter-based therapies for the treatment of coronary artery disease. Usually, a LIMA graft to the LAD is placed in concert with PCI of non-LAD targets. Generally, the LIMA to LAD graft is performed using a minimally invasive technique (e.g., MIDCAB or TECAB, described in the earlier sections of this chapter). The hybrid concept can be extended to the treatment of combined coronary and valve diseases, such as a minimally invasive valve surgical procedure combined with PCI to coronary lesions with the intention, for example, of converting a high-risk valve/CABG into a lower risk minimally invasive valve procedure, but these applications are not discussed here.

Rationale and Background

The hybrid approach attempts to “bring the best of two worlds” of cardiac surgery and interventional cardiology together by combining the most effective treatment strategies from the two disciplines for the treatment of multivessel coronary artery disease.

It has been well shown that the LIMA to LAD graft is the most effective and durable option for anterior wall revascularization, primarily because of its resistance to thrombosis and atherosclerosis. The LAD supplies the largest area of myocardium (including the anterior wall and septum) of any of the coronary arteries, and the LIMA to LAD graft is known to improve survival, with 5-year patency rates between 92% and 95% and 10-year patency rates between 95% and 98%.³¹ Such proof is lacking for PCI of the LAD. On the contrary, PCI with drug-eluting stents (DESs) offers equal if not better revascularization durability compared with vein and radial artery grafts. One-year saphenous vein graft (SVG) failure rates range between 7% and 30%; 40% to 50% of SVGs will fail or become atherosclerotic by 15 years.³¹

With these factors in mind and in the context of the developing minimally invasive surgical procedures (most particularly suited to the LIMA to LAD anastomosis, such as MIDCAB and TECAB), interest in the potential advantages of hybrid approaches grew beginning in the late 1990s and continuing over the first decade of 2000. Angelini and colleagues reported the first series of six patients, treated with a MIDCAB LIMA to LAD and PTCA or PTCA and stent in 1996. A decade later, a multicenter international trial on the feasibility of coronary hybrid procedures showed the basic feasibility of combining robotic TECAB and PCI.³² Twenty-seven patients requiring double-vessel revascularization were treated with TECAB LIMA-LAD, and PCI to non-LAD targets (bare-metal stent [BMS] or DES). Three-month follow-up angiography showed an excellent LIMA-LAD patency of 96.3% but a lower than expected PCI patency of 66.7%. No deaths or strokes were observed. One

patient suffered a perioperative myocardial infarction. The early reintervention rate, primarily as a result of stent failures, was 29.3%.

Technical and Timing Issues of Hybrid Interventions

Hybrid procedures generally involve a MIDCAB or TECAB surgical procedure for creation of the LIMA to LAD anastomosis along with catheter-based PCI intervention(s). The timing of the surgical procedure in relation to the percutaneous intervention has been a subject of some discussion.

By their nature, all hybrid procedures are staged; only the duration of the staging period and the order in which the procedures are performed can be varied. Two-staged hybrid procedures are those in which PCI and CABG are performed in separate operative locations. The two procedures can be separated by hours, days, or weeks. One-stop procedures are performed in one setting, and the procedures are separated by minutes.³³ In a two-stage hybrid procedure, either the surgical procedure or the percutaneous intervention can be performed first. In a one-stop or simultaneous procedure, the surgical intervention is generally performed first.

The advantages and disadvantages of each approach are discussed next. Each has its theoretical relative merits and drawbacks. At present, there are no data to support any of the approaches above the others; clinicians must weigh the relative merits of each strategy in the context of their practice setting and the clinical scenarios they encounter.

Percutaneous Intervention prior to Surgical Intervention

Performing the percutaneous revascularization before surgical revascularization is associated with several potential advantages. First, the revascularization of the non-LAD targets provides collateral circulation and decreases the risk of ischemia if LAD occlusion is used in the beating heart surgical approach. Second, it allows the interventionalist the opportunity for aggressive multivessel revascularization knowing that if a complication occurs or PCI is not successful, a conventional CABG can be performed at a later time. Most patients who are treated with a “PCI first” approach undergo an acute percutaneous intervention of the culprit lesion for acute coronary syndrome, and the LIMA to LAD graft is placed using a less invasive approach at a later time point.

This approach is associated with a number of disadvantages. It necessitates performing PCI in a setting in which no protection is afforded by a LIMA to LAD graft. Also, unless a third procedure (completion angiogram) is performed after the surgical procedure, no mid-term angiographic imaging of the LIMA-LAD graft is afforded by this sequence of procedures. Most important, the risk of stent thrombosis and need for antiplatelet agents following PCI necessitates either performing the minimally invasive surgical revascularization on clopidogrel (which has been associated with a slightly increased risk of bleeding¹) or maintaining hospital patients on eptifibatide

(Integrilin; Schering-Plough, Kenilworth, NJ) until their surgical intervention.^{1,33}

Surgical Intervention prior to Percutaneous Intervention

Performing PCI after LIMA-LAD grafting makes it possible to avoid antiplatelet-related bleeding complications during the surgical procedure; antiplatelet therapy can be started after surgery and continued long term, in keeping with current recommendations following stent implantation. In addition, the percutaneous interventions can be performed with the protection afforded by the surgical revascularization, allowing interventionalists to more safely approach, for example, left main or diagonal bifurcation lesions.¹ A final benefit to this approach is that it allows for the LIMA-LAD anastomosis to be angiographically evaluated at the time of PCI. However, if there is a complication or failure of the PCI, a second, higher risk operation needs to be performed. This should be a rare occurrence, however, because the incidence of emergent CABG following PCI is less than 1%.¹ Given these considerations, most cardiologists and surgeons who perform two-staged hybrid procedures have adopted this strategy.

At present, the optimal duration of time between the two interventions is unclear. Patients should at least be able to tolerate lying flat on the angiography table, which, because of postoperative respiratory compromise, could take several days. It also seems reasonable to delay PCI until the inflammatory milieu that exists immediately after surgery resolves. This usually requires 3 to 5 days, but patients may need 7 to 10 days of mental and physical recovery following surgery. Ideally, PCI would be performed at the index hospitalization so that the patient would not be discharged without being fully revascularized, but economic issues can make this problematic if long postsurgical recovery periods are required.¹

Simultaneous Procedures

Two-staged procedures involve two teams, logistical challenges, the costs associated with two separate procedures, and possible hospitalization between the procedures. In addition, many patients would simply prefer not to undergo two separate interventions.³³ In centers with hybrid operating rooms where both percutaneous and surgical procedures can be performed, a one-stop procedure can be performed.

In this approach, there is superb monitoring throughout the procedure under general anesthesia, any complications encountered can be resolved in one setting, and a completion angiogram can be done to evaluate the LIMA-LAD graft. Complete revascularization is accomplished before leaving the operating suite, and the patient experiences the emotional and psychological benefit of a complete “fix” in one anesthetic setting.¹ Potential drawbacks include the need for specialized hybrid facilities, increased operative times, and higher cost with inadequate hospital reimbursement. Concerns about performing PCI in the inflammatory milieu created by the surgical

bypass have been raised, and bleeding risk remains a concern because full antiplatelet therapy and incomplete (or no) heparin reversal are practiced after the combined procedure. At this point, the data regarding the effect of clopidogrel on bleeding in patients undergoing hybrid procedure are mixed (with some reporting increased bleeding and others reporting no such increase³⁴⁻³⁶), and the effects of protamine reversal on stent patency are unknown.

The timing of PCI related to TECAB in a hybrid procedure was recently investigated by Srivastava and colleagues.³⁷ The group retrospectively reviewed 238 patients submitted to hybrid treatment over a 10-year period. Most patients (73%) underwent TECAB before PCI. Overall, the authors observed no drastic impact of PCI timing on outcomes, but patients submitted to PCI before or at the same time as TECAB experienced shorter intensive care unit and hospital lengths of stay in comparison with patients who had surgery first. The authors concluded that timing of interventions can be individually tailored to patients' needs.

Current State of Hybrid Revascularization and Recent Information

At the time of this publication, experience with this technique remains limited. No prospective randomized trials on hybrid revascularization have been published, and only three series with triple-digit numbers of patients have been reported.³⁸

The small amount of data available on the subject show a low mortality rate (up to 2%) and a low overall morbidity rate (average of $\approx 4.7\%$ in hospital morbidity across all studies), with shorter hospital and intensive care unit stays than would be expected with conventional CABG.³³ Immediate LIMA to LAD patency rates range from 92% to 100%.³³ With respect to restenosis rates, the data are mixed. Earlier series, which made use of BMSs or angioplasty without stenting, revealed higher 6-month stent restenosis rates so that in the entire experience thus far, these rates range from 2.3% to 23%, with an average of 11% across all of the literature.³³ However, in one series in which only DESs were used in procedures combining MIDCAB and PCI, 97% 1-year patency rates were reported.³⁶

In the largest reported series of robotically assisted hybrid coronary interventions on 226 patients with 5-year follow-up, a 1.3% hospital mortality rate, average hospital stay of 6 days, and a 92.9% 5-year survival rate were found. Five-year freedom from major adverse cardiac and cerebral events was 75.2% and reintervention rates were 2.7% with respect to bypass grafts and 14.2% with respect to PCI targets.³⁸

Given the limited data available to evaluate hybrid revascularization, as well as the evolving nature of both minimally invasive surgical approaches and percutaneous therapies, generalized statements regarding outcomes are difficult to make at this time. Additional studies are needed to fully evaluate this approach.

THE FUTURE OF CORONARY REOPERATIONS

Reoperations present coronary surgeons with their greatest challenges. Patients undergoing reoperation for bypass grafting are different from those who undergo primary surgery. In addition to the risks of a repeated median sternotomy, their coronary artery and noncardiac atherosclerosis is more advanced, noncardiac comorbidities are more common, ventricular function is more likely to be abnormal, and the vascular pathologic processes that jeopardize myocardium are distinct and varied.¹⁻⁴ All these issues present specific technical challenges.

In addition to the technical difficulties presented by reoperations, decision making is not perfectly straightforward. No major randomized trials have studied patients with prior bypass surgery. In only a few situations do observational studies indicate that reoperative coronary surgery improves prognosis.⁵ For many patients, percutaneous intervention is an appealing prospect, but unfortunately the results of percutaneous treatment of patients with prior surgery have been suboptimal even in the era of drug-coated stents.⁶⁻⁸

The reasons that patients need coronary reoperations have their anatomic bases in an ineffective first operation, bypass graft failure (early or late), progression of atherosclerosis in native coronary arteries, failure of interventional procedures, and combinations of these problems. The relative contributions of these factors have changed with the evolution of bypass surgery and with the evolution of alternative treatments for coronary atherosclerosis. Today, early vein graft failure, although not rare, is rarely an indication for early reoperation. First,

percutaneous interventions are usually available to treat symptomatic patients who experience vein graft failure. Second, as long as an internal thoracic artery (ITA) to left anterior descending (LAD) graft is functioning, sufficient indications for early reoperation are rarely present even if other grafts are imperfect. Early reoperations are usually indicated only in the situation of both ITA and vein graft failure. Late reoperations are usually indicated by a combination of progression of native vessel atherosclerosis and vein graft failure, usually based on the occurrence of vein graft atherosclerosis.

The pathologic changes of vein grafts are important, not only as causes of reoperations but also as causes of events associated with medical or interventional treatment.^{9,10} Early vein graft occlusion is usually associated with intimal disruption and thrombosis. Within 2 to 3 months of surgery, a proliferative intimal fibroplasia develops in most vein grafts. This concentric, diffuse, cellular lesion becomes more fibrous with time, possibly as an adaptive response to arterialization. It usually does not cause stenosis or occlusion. The most recent data indicate an occlusion rate of 6.2% at 1 year after operation. In that study, the use of statins and beta blockers were associated with a decreased risk of intimal fibroplasia (defined by interventional ultrasound) and graft occlusion.¹¹ Within a few years of operation, lipid deposition can occur in association with intimal fibroplasia, and the resulting lesion is termed *vein graft atherosclerosis*. The fully developed lesion of vein graft atherosclerosis is different from native vessel atherosclerosis. Vein graft

atherosclerosis is superficial, nonencapsulated, diffuse, and concentric. It is an extremely friable lesion and is much more prone to embolization than is native vessel atherosclerosis. In addition, clinical studies appear to show that it is more consistently progressive than is true of native vessel atherosclerosis, as vein graft stenoses caused by vein graft atherosclerosis predict a high level of clinical events. Patients with coronary risk factors such as hyperlipidemia and diabetes appeared to experience an increased incidence of vein graft atherosclerosis and graft failure.¹² There is now evidence that treatment with platelet inhibitors and statins decreases the rate of late vein graft failure. However, even with these measures, vein graft atherosclerosis has not been eliminated.

ITA grafts rarely develop atherosclerosis, and the patency rate of ITA grafts, particularly to the LAD coronary artery, exceeds that of vein grafts.¹² The use of ITA to LAD grafts at primary operations clearly decreases the risk of reoperation during the first 10 postoperative years, and the use of both ITA grafts further decreases the risk of reoperation (Fig. 91-1).^{4,13,14} Furthermore, although patent ITA grafts present technical challenges at reoperation, atherosclerotic embolization is not as high a risk as it is for patients with patent but atherosclerotic vein grafts.

For patients undergoing primary bypass surgery, the likelihood of undergoing a reoperation will depend on the length of their life, the severity of the atherogenic diathesis, the effectiveness of the treatment of that diathesis, the details of the primary operation, the alternative therapies available, and the physician's and patient's preferences. A review of patients undergoing primary bypass surgery at the Cleveland Clinic between 1971 and 1974 documented a 25% chance of reoperation by 20 postoperative years.¹⁵ Today we would expect that figure

FIGURE 91-1 ■ Predicted freedom from reintervention after primary isolated coronary artery bypass graft stratified by single, double, or no internal thoracic artery (ITA) grafting at primary operation. Solid lines represent parametric estimates enclosed within dashed 68% confidence limits (± 1 SE). (Reprinted with permission from Sabik JF III, Blackstone EH, Gillinov AM, et al: Influence of patient characteristics and arterial grafts on freedom from coronary reoperation. *J Thorac Cardiovasc Surg* 131:90–98, 2006.)

to be much less as the number of isolated coronary reoperations performed has declined. The Society of Thoracic Surgeons database noted 16,091 isolated coronary reoperations reported in 1998, compared with 8820 in 2000 and 5734 in 2009.¹⁶ The reasons for this decline probably include the increased use of ITA grafts at primary operation, better risk factor control producing less progressive vein graft atherosclerosis, and the use of stents to treat vein graft lesions.

INDICATIONS FOR CORONARY REOPERATIONS

The randomized trials of bypass surgery versus medical management or percutaneous coronary intervention did not include patients with previous surgery. Furthermore, patients with previous surgery are extremely heterogeneous, their vascular pathologic processes being multiple and their extent of revascularization not always falling into the categories of single-, double-, and triple-vessel disease. In particular, vein graft atherosclerosis is a more progressive vascular disease, and the presence of vein graft atherosclerosis predicts a particularly unfavorable clinical outcome without repeated surgery. Thus, there is relatively little clarity in terms of the indications for reoperation. Observational studies, however, have provided some important information.

- Early stenoses in vein grafts (<5 years after operation) do not predict unfavorable outcomes if patients are not highly symptomatic.^{5,10} Therefore, an early stenosis in a vein graft is not necessarily an indication for either reoperation or reintervention.
- Patients with early stenoses in vein grafts who are highly symptomatic often exhibit marked improvement after reoperation.⁵
- Late (>5 years after operation) stenoses in vein grafts do predict adverse outcomes when patients are managed medically, particularly if the stenotic vein graft subtends the LAD coronary artery or if multiple vein grafts are involved.^{5,10}
- Late stenoses in vein grafts are more consistently progressive than native vessel stenoses are.¹⁰
- Reoperation can improve the survival rate of patients with late stenoses in vein grafts, particularly if that late stenosis involves a vein graft subtending the LAD coronary artery (Fig. 91-2).⁵
- Patients with late stenoses in vein grafts who do have significant symptoms can usually experience improved symptoms after reoperation.⁵
- Patients with a patent and effective ITA-to-LAD graft who are not highly symptomatic have not been shown to have an improved survival rate with reoperation.⁵

As has been true of patients undergoing primary bypass surgery, functional studies could add to the accuracy of identifying patients who are likely to have unfavorable outcomes without reoperation. Patients who demonstrate ischemia and an impaired exercise capacity are at greater risk for death and cardiac events without reoperation than are those with negative or only mildly positive stress test results.¹⁷

FIGURE 91-2 ■ Comparison of late survival rates for patients with late stenoses of more than 50% in vein grafts subtending the left anterior descending coronary artery shows a distinct survival advantage for patients undergoing reoperation. (Reprinted with permission from Lytle BW, Loop FD, Taylor PC, et al: The effect of coronary reoperation on the survival of patients with stenoses in saphenous vein bypass grafts to coronary arteries. *J Thorac Cardiovasc Surg* 105:605–612, 1993.)

SUMMARY OF CURRENT INDICATIONS FOR TREATMENT OF PATIENTS WITH PREVIOUS BYPASS SURGERY

In the absence of contraindications, all patients with previous bypass surgery should be treated with platelet inhibitors, statin-type drugs, and control of risk factors including hypertension, diabetes, and hyperlipidemia. The indications for more invasive treatment are related to symptom relief and, in some circumstances, improvement of prognosis.

Significant late stenoses in multiple vein grafts or in a vein graft to the LAD coronary artery predict an unfavorable prognosis that can be improved by reoperation; therefore, they constitute a strong indication for repeated surgery. The indications for reoperation in these anatomic situations are particularly strong when they are associated with abnormal left ventricular function, a positive stress test result, and a clear demonstration of myocardium in jeopardy. The presence of multivessel disease jeopardized by native vessel lesions and vein graft disease that includes a proximal LAD lesion also seems to constitute an indication for reoperation for improvement of prognosis. There has not yet been a clear demonstration that reoperation improves the survival rate of patients who have a patent, effective ITA-LAD graft. Severe symptoms of angina combined with severe stenoses in native coronary arteries or grafts subtending areas of viable myocardium constitute good indications for surgery for the purpose of symptom relief.

The availability of percutaneous coronary treatments can be an advantage in the symptomatic treatment of patients with previous bypass surgery. Native vessel disease in particular, when accessible, can be effectively treated with stenting, and in the current era of drug-coated stents, it is often effective. The treatment of vein

graft disease with percutaneous intervention has, unfortunately, not been effective in the long term even with the use of drug-coated stents.^{8,18–20} However, despite those issues, it is still reasonable to use stenting for treatment of symptomatic vein graft disease when large amounts of myocardium are not jeopardized and symptom relief is the goal. There is no evidence that the treatment of vein graft disease with percutaneous intervention achieves any improvement in prognosis in any situation.

Comparisons of surgical and percutaneous treatments for heterogeneous groups of patients with previous bypass surgery have shown roughly equivalent outcomes. However, these studies have been small in number and have not separated patients into subsets based on the vascular pathologic process needing to be treated and prognostic subgroups based on coronary and vein graft anatomy. Therefore, the relative use of reoperation and percutaneous coronary treatment for the anatomic treatment of patients with previous bypass surgery will depend on multiple factors, including the vascular pathologic process producing the ischemia, the general health of the patient and specific contraindications to surgery, the function of the left ventricle, the area of myocardium in jeopardy, and the experience of the surgical and interventional teams.

TECHNICAL ASPECTS OF CORONARY REOPERATIONS

Reoperations are more difficult than primary operations. Some of that difficulty relates to similar but more extreme pathologic processes that are encountered at reoperation, whereas some problems are unique to reoperations. Potential technical problems during coronary reoperations include sternal reentry, aortic atherosclerosis, atherosclerotic vein grafts, patent arterial bypass grafts, diffuse native coronary artery disease, lack of bypass conduits, locating coronary arteries, and myocardial protection. The most common cause of in-hospital death after coronary reoperation is perioperative myocardial infarction. Those myocardial infarctions are often anatomically based; their causes include injury to bypass grafts, atherosclerotic embolization from vein grafts or from the aorta, myocardial devascularization after graft removal, hypoperfusion through new grafts, incomplete revascularization, early graft occlusion, air embolization, technical error, and inadequate myocardial protection. The planning for reoperation and the intraoperative conduct of the procedure must be designed to avoid these anatomic causes of perioperative myocardial infarction.

PREOPERATIVE ASSESSMENT

The first step in reoperative coronary surgery is a complete coronary angiogram that delineates native coronary and graft anatomy. That step is not as easy as it sounds. If bypass grafts are not demonstrated by a preoperative coronary angiogram, it may be that those grafts are occluded, but it is also possible that the angiographer failed to inject them. A copy of the previous operative

note can be important in describing the location of bypass grafts, and it can be helpful to examine old angiograms to identify important coronary arteries and to help understand the previous operative notes. Coronary arteries do not disappear, and a large vessel that was present previously must be accounted for on the current angiogram.

To accomplish symptom relief and improvement of prognosis, there must be a match between graftable coronary arteries and viable myocardium. It is important to establish the state of the myocardium preoperatively by thallium scanning, positron emission tomography, stress echocardiography, or magnetic resonance imaging. Bypass grafts performed to nonviable myocardium do not improve prognosis.

It is important to know which bypass graft conduits will be available. Doppler studies can be used to establish ITA patency, but if the goal of the operation is to use one or both ITAs to bypass important coronary vessels, then it is best to establish their patency with angiography. Venous Doppler studies can be used to assess the presence of greater and lesser saphenous vein grafts, and arterial Doppler studies can assess radial artery status.

Based on studies of intraoperative events, their implication, and the likelihood of rescue once adverse events have occurred, we perform preoperative computed tomographic scanning for all patients undergoing reoperation at the Cleveland Clinic.²¹

MEDIAN STERNOTOMY, CONDUIT PREPARATION, AND CANNULATION

A median sternotomy is the best incision for most coronary reoperations. If computed tomographic scanning demonstrates an increased risk of sternal reentry—those situations including right ventricular enlargement, a patent vein graft to the right coronary artery, an in situ right ITA graft to a left coronary vessel, an in situ left ITA graft that is directly beneath the sternum, aortic enlargement, multiple previous operations, and an injury during a previous sternal incision—we obtain arterial and venous access before reopening the sternotomy (Fig. 91-3). In addition, we prepare the radial artery and saphenous vein segments that are going to be used for bypass grafting before that sternotomy. In difficult situations, cardiopulmonary bypass can be established before a sternotomy is performed, but that is not our usual strategy. We prefer to avoid full heparinization before the dissection and before preparation of the right internal mammary artery. We commonly cut the sternal wires anteriorly but leave them intact posteriorly, and an oscillating saw is used to divide the anterior table of the sternum (see Fig. 91-3). Once that is accomplished, ventilation is stopped, the assistants elevate each side of the sternum with retractors, and the posterior table is divided. We then remove

FIGURE 91-3 ■ Strategies for safe sternal reentry during coronary reoperations include (a) axillary artery cannulation for arterial access, (b) femoral venous cannulation to allow institution of cardiopulmonary bypass and to avoid manipulation of an atherosclerotic saphenous vein graft to the right coronary artery, (c) leaving the sternal wires intact posteriorly and using an oscillating saw to reopen the sternum, and (d) a small anterior right thoracotomy to allow safe separation of the right ventricle from the sternum. (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2009. All rights reserved.)

the wires once the sternum has been completely divided, because they serve to protect underlying structures. In difficult situations, a small anterolateral right thoracotomy can be performed to facilitate dissection of the heart or the aorta away from the sternum (see Fig. 91-3).

Once the sternum is opened, adhesions are lysed starting at the diaphragmatic level, extending the dissection into the thoracic cavities in a cranial direction. Working from the level of the diaphragm in the cranial direction is the safest approach to avoid graft injury. Superiorly, the innominate vein is freed from the sternum on both sides to prevent a stretch injury. Once the sternum is dissected away from the mediastinal structures, the ITAs are prepared. If there is a patent left ITA graft in place, it is separated from the chest wall. The risk of injury to a patent left ITA graft is established by the location in which the graft is placed at the time of the primary operation. At primary operations, the pericardium should be divided posteriorly and the left ITA is allowed to run posterior into the pericardium. In this location, it is out of danger at reoperation.

Intraoperative echocardiography is used to examine the function of the aortic and mitral valves, intraoperative left ventricular function, and extent of atherosclerosis of the ascending aorta and aortic arch. In the presence of ascending aorta atherosclerosis or lack of room on the ascending aorta, alternative arterial cannulation sites include the axillary artery and the femoral artery. However, for patients undergoing reoperation, the extent of the atherosclerosis really means that the iliofemoral vessels are not ideal for cannulation, and the axillary artery is the preferred site (see Fig. 91-3).

It is important to avoid manipulation of atherosclerotic vein grafts during the dissection of the heart; doing so can result in the embolization of atherosclerotic debris into the distal coronary system and the occurrence of myocardial infarction. This is a specific danger during reoperation, and although a true “no-touch” technique may be difficult to achieve, manipulation of grafts should be minimized.^{1,22,23} To avoid manipulation of an atherosclerotic vein graft to the right coronary artery, it is sometimes wise to cannulate the right atrium through the femoral vein (see Fig. 91-3). When atherosclerotic right-sided grafts are absent, we usually use a two-stage venous cannula through the right atrium into the inferior vena cava for venous cannulation.

When a patent left ITA graft is present, we try to isolate it so that it can be occluded with an atraumatic clamp. This is an aid in myocardial protection as long as we can deliver retrograde cardioplegia. When the location of a patent left ITA graft is not clear, the tissue between the aorta and the left lung is isolated by dissecting posteriorly on the medial aspect of the left lung and on the left lateral aspect of the aorta. We then use an atraumatic clamp across that tissue, which usually includes the left ITA graft.

Once arterial and venous cannulation has been accomplished, we can begin cardiopulmonary bypass and place a retrograde coronary sinus cardioplegia cannula through the right atrium into the coronary sinus. The temperature is then cooled to 34° C, and the aorta is cross-clamped and antegrade cardioplegia is given, followed by

retrograde cardioplegia. Adequacy of the delivery of retrograde cardioplegia is assessed by the pressure in the coronary sinus, the rate of cooling of the heart, and the degree of distention of the cardiac veins. If retrograde cardioplegia delivery is effective, it is used throughout the rest of the case.²² The dissection of the left ventricle is accomplished once the heart has been arrested. This strategy leads to an accurate dissection that is atraumatic to the epicardium and decreases the bleeding as well as the amount of manipulation of any atherosclerotic vein grafts. Furthermore, it aids in the identification and isolation of a patent ITA graft. If we are unable to isolate the ITA graft before aortic cross-clamping, we dissect along the diaphragm to the left side of the apical portion of the LAD coronary artery and then continue proximally to the left of the patent ITA graft. That graft will be included in the strip of pericardium, and it can be clamped.

If it is impossible or dangerous to dissect out and control the left ITA graft, we then decrease the systemic temperature usually to 20° C to achieve cardiac arrest and myocardial protection. We believe, however, that this strategy is inferior to being able to occlude the ITA graft and give retrograde cardioplegia. A study comparing these strategies did not show different outcomes although operative mortality rates were 7% to 8% in both groups.²⁴

Once the heart has been arrested and dissected out, the coronary vessels that are to be grafted are identified. Again, it is important to have a previous operative note and a clear coronary angiogram to help identify these vessels. Previously constructed bypass grafts can be tracked to their point of insertion, which often helps identify vessels, particularly those that are intramyocardial. Intramyocardial vessels often provide the best sites for anastomoses as they have less atherosclerosis than epicardial vessels.

STENOTIC VEIN GRAFTS AND GRAFTING PATTERNS

The management of atherosclerotic but patent or stenotic vein grafts is a major issue during reoperation. Ideally, any atherosclerotic vein graft should be replaced at a reoperation to prevent atherosclerotic embolization at the time of surgery or late progression and graft failure thereafter. However, graft replacement might not be possible because of the lack of bypass conduits. If patent or stenotic saphenous vein grafts (not totally occluded) are removed at the time of operation, it is important to replace them with grafts of equal size and flow to avoid hypoperfusion.²⁵ That usually means replacing stenotic vein grafts with other vein grafts. If only arterial grafts are available, it is usually the best idea to add an arterial graft to the coronary artery and leave the vein graft intact. A concern about the second strategy is that persistent flow through the old saphenous vein graft might create enough competitive flow to produce an atretic arterial graft. That usually does not occur if the vein graft has a stenosis of more than 50%.

When arterial grafts are available, they can often be used effectively during reoperation.¹ If the left ITA has

not been previously used, it usually functions well as an in situ graft. The right ITA is more difficult to use as an in situ graft at reoperation because of limitations in its length, and in most instances it is better used as a “free” graft with a proximal anastomosis to the aorta, a new left ITA graft, or a previously constructed left ITA graft. If there is a previously constructed left ITA graft that is patent, it has often increased in size and is capable of providing good inflow (Fig. 91-4). The use of a patent left ITA graft for a proximal right ITA graft site allows the length of the right ITA to be maximized. Short segments of the left ITA or other arterial grafts can be used to bridge distal LAD stenoses (see Fig. 91-4).

In constructing proximal anastomoses of arterial grafts to the aorta, we try to use the hood of a new or an old vein graft as the anastomotic site, because a direct arterial graft anastomosis to the thickened reoperative aorta can be difficult.

Alternative arterial bypass grafts, such as the radial artery, the gastroepiploic artery, and the inferior epigastric artery, can also have roles during reoperations. The radial artery is a large vessel that can be used as a single graft from the aorta to almost any coronary artery and sometimes as a sequential graft. Early (<5 years) patency studies show a favorable patency rate for radial artery grafts, but only time will tell their ultimate usefulness. The inferior epigastric artery is not a long vessel, but it can be helpful during reoperations as a composite graft. The gastroepiploic artery as an in situ graft can be useful for grafting the posterior descending branch of the right

coronary artery or the distal anterior descending coronary artery.

DIFFERENTLY INVASIVE STRATEGIES FOR REOPERATIVE CORONARY SURGERY

Although most reoperations are best performed through a median sternotomy because of the need to reach multiple regions of the heart, alternative reoperative strategies can provide an advantage in specific situations. Substantial proportions of primary operations are performed without the use of cardiopulmonary bypass, and this off-pump approach is appropriate for some reoperations. A disadvantage of reoperative off-pump surgery lies in the danger of manipulating patent but atherosclerotic vein grafts during dissection of the heart and causing embolization of atherosclerotic debris into coronary arteries. If all grafts are occluded, this is not a risk.

Target vessel revascularization strategies in which limited areas are approached through alternative incisions and off-pump surgery is performed may be effective because the extensive epicardial dissection that can cause embolization is not needed. An increasingly common operation is to graft the circumflex coronary artery through a left thoracotomy with either a radial artery or saphenous vein graft anastomosed to the descending thoracic aorta or subclavian artery and then to the circumflex artery, usually using an off-pump strategy (Fig. 91-5). This approach avoids the risk of damaging a patent left ITA-LAD graft and avoids cardiopulmonary bypass. The disadvantages of this strategy are that intramyocardial circumflex vessels can be difficult to locate, the descending aorta may be atherosclerotic and a difficult site for a proximal anastomosis, and it makes use of the right ITA difficult. When the left ITA is patent to the LAD coronary artery and there is a major circumflex branch available for grafting, it is usually our intent to use the right

FIGURE 91-4 ■ Multiple grafting strategies are often useful at reoperation. A new or previously placed left internal thoracic artery graft (a) can be used as inflow to maximize the length available for a free right internal thoracic artery graft (b) or a small arterial graft segment (c) used to bridge a distal left anterior descending stenosis. The hood of a previously placed vein graft (d) is often the best location for a new arterial free graft or a vein graft. FIGURE 91-5 ■ A left thoracotomy can be used for an off-pump anastomosis of a radial artery or vein graft to the circumflex coronary artery. (Reprinted with the permission of the Cleveland Clinic Center for Medical Art & Photography © 2009. All rights reserved.)

ITA to graft that circumflex vessel, thus maximizing long-term benefit.

The gastroepiploic artery can be used as an in situ graft to graft the posterior descending branch of the right coronary artery through the diaphragm with a small distal sternotomy or transdiaphragmatic approach or the anterior descending coronary artery through a distal sternotomy or small left thoracotomy. The left ITA can be used to graft the anterior descending coronary artery through a small left thoracotomy (minimally invasive direct coronary artery bypass), and the right ITA can be used to graft the anterior descending artery as an in situ graft through a repeated median sternotomy. These strategies can be useful in specific situations in which the goal is limited revascularization. However, most patients who are reoperative candidates need multiple grafts to multiple vessels.

RESULTS OF CORONARY REOPERATIONS

Coronary reoperations have been associated with higher risks of death and in-hospital complications than primary coronary surgery has.^{1,3,16,23,26-29} Some of the mortality risk appears to be associated with the technical difficulty of the reoperative situation and some with the higher-risk characteristics of reoperative candidates. Studies from institutions with a high level of experience with reoperation have shown that when patient-related characteristics are adjusted for the reoperative situation itself, risk does not appear to be increased, at least in more recent years.²⁶⁻²⁷ On the other hand, studies of broader databases, such as the New York State database, show that reoperation still persists as a specific risk factor in coronary surgery.³ Coronary reoperations are difficult, and it is possible that patients undergoing these procedures at institutions with a high level of experience have better outcomes and that the specific risks of reoperation can be ameliorated with experience.

A query of the Society of Thoracic Surgeons database, which is probably most reflective of widespread practice, shows a decrease in the mortality risk of coronary reoperations from 6.1% in 1998 (542 deaths of 8820 patients) to 4.6% (261 deaths of 5734 patients) in 2009.¹⁶ It is important to note that the absolute numbers of reoperations have decreased, while the proportion classed as urgent increased during that time interval. It is likely that patient selection and acuity classification changed during that interval. The acuity of the operation has always played a defining role in the prediction of hospital mortality and still does. In the Cleveland Clinic series, the risk of hospital mortality for isolated reoperative bypass surgery was 1.7% in 1998 (5 of 291), 1.5% in 2007 (1 of 67), and 1.5% (22 of 1505) during those years cumulatively, whereas urgent reoperations carried a risk of 3.7% (15 of 401) overall. Thus, in any setting, reoperations in situations of increased acuity generate increased risk.

Other factors that increase the risk of coronary reoperations include advanced age, left ventricular dysfunction, and renal failure. In the past, some of the factors specifically associated with the reoperative situation,

including patent ITA grafts and atherosclerotic vein grafts, have been associated with increased risk; however, with the passage of time, the effects of those variables have either decreased or been eliminated. Presumably that has resulted from increased experience and the technical modifications of reoperations, such as the use of retrograde cardioplegia (a factor specifically associated with decreased mortality), minimal manipulation of vein grafts, alternative cannulation sites, and the many other technical modifications used to deal with the reoperative situation.

The late results of reoperation are not as favorable as those after primary procedures. Realistically, reoperations do not make patients as “perfect” as primary operations often do. Few reoperative candidates undergo true complete revascularization, and most have severe native coronary artery disease at the time of their reoperation. It is not surprising, therefore, that anginal symptoms are more common after reoperation than they are after primary bypass surgery. Follow-up of our series of reoperative patients at a mean interval of 72 months after operation showed that 64% of patients were classified as New York Heart Association functional class I, meaning that more than one third had some symptoms.²⁸ It is true that few patients had severe symptoms, but some angina was present in about one third of patients. Other institutions have also noted a high level of angina recurrence after reoperation.

The late survival rates after reoperation are not as good as those documented after primary surgery. Weintraub and colleagues from Emory University documented a 55% 10-year survival rate and more recently noted diabetes to be a specific risk factor decreasing the late survival rate after both reoperation and percutaneous coronary treatment for patients who have had previous bypass surgery.^{2,29} The increased prevalence of diabetes, left ventricular dysfunction, and advanced age in the reoperative population can be expected to correlate with a decrease in late overall survival rates.

MULTIPLE CORONARY REOPERATIONS

Patients with more than one previous bypass operation present incremental problems. A lack of bypass conduits is common, and virtually all patients have highly diffuse native vessel disease. Hospital risks have been increased for patients undergoing third or fourth procedures. In our early experience, we noted an 8% mortality rate of third operations, although more recently the risks for patients younger than 70 years have decreased to 1% to 2%.³⁰ Likewise, the long-term survival rate is not as favorable, although in our most recent follow-up, 84% of patients with multiple previous operations were alive at 5 years and 66% at 10 years after operation.

COMPLEMENTARY END-STAGE REVASCULARIZATION PROCEDURES

Substantial investigations have been directed toward indirect revascularization strategies that might apply to

patients with coronary atherosclerosis so diffuse that neither bypass grafting nor percutaneous coronary treatment will result in complete or effective revascularization. Most patients judged as candidates for these strategies have had previous bypass surgery.

Transmyocardial laser revascularization (TMLR) has been shown with randomized (although not blinded) trials to improve the symptom status of patients receiving only TMLR or TMLR in combination with bypass grafting. We rarely use TMLR in isolation, but we do use it in combination with bypass grafting during reoperation.

THE FUTURE OF CORONARY REOPERATIONS

A huge wave of patients needing coronary reoperations, once feared, has not materialized. However, recurrent ischemic syndromes after bypass surgery are common and are related to time. Despite advances in pharmacologic and interventional therapies for coronary atherosclerosis, many patients still require reoperation, and they present coronary surgeons with their most difficult challenges.

ISCHEMIC MITRAL REGURGITATION

Anelechi C. Anyanwu • Javier G. Castillo • Amit Arora • David H. Adams

CHAPTER OUTLINE

DEFINITION

CLINICAL PRESENTATION

PATHOPHYSIOLOGY

Specific Geometric Abnormalities

- Annular
- Subvalvular
- Left Ventricular
- Leaflet Dysfunction

THERAPEUTIC TARGETS IN ISCHEMIC MITRAL REGURGITATION

- Coronary Artery Disease
- Mitral Annulus
- Subvalvular Apparatus
- Leaflets
- Left Ventricle

PREOPERATIVE DECISION MAKING

Decision Making in Specific Clinical Scenarios

- Severe Ischemic Mitral Regurgitation with Congestive Heart Failure
- Mild or Moderate Ischemic Mitral Regurgitation in Patients Undergoing Coronary Artery Bypass Grafting

OUTCOMES

- Effect of Ischemic Mitral Regurgitation on Survival after Myocardial Infarction
- Effect of Ischemic Mitral Regurgitation on Survival after Percutaneous Coronary Intervention
- Effect of Ischemic Mitral Regurgitation on Survival after Coronary Artery Bypass Grafting
- Coronary Artery Bypass Grafting Alone or with Mitral Valve Intervention

TYPE II ISCHEMIC MITRAL REGURGITATION

Acute Papillary Muscle Rupture

Chronic Type II Ischemic Mitral Regurgitation

Significant advances have been made in the treatment of ischemic cardiomyopathy; however the presence of mitral regurgitation in this population continues to be a significant risk factor for mortality.¹ This chapter addresses the current concepts regarding the pathophysiology, decision making, and treatment of ischemic mitral regurgitation.

DEFINITION

Carpentier's pathophysiologic triad² is our preferred approach for defining ischemic mitral regurgitation. Most of the clinical literature on ischemic mitral regurgitation remains difficult to interpret because imprecise definitions

are often applied, which leads to marked heterogeneity within and between patient populations. A precise and uniform definition of ischemic mitral regurgitation is critical to the presentation of a relatively homogeneous group of patients for analysis and treatment.³ A strict definition of ischemic regurgitation according to the pathophysiologic triad typically requires the following:

- The *etiology* in this process is ischemic heart disease. This typically requires demonstration of coronary artery atherosclerosis *and* evidence of prior myocardial infarction with regional or global dysfunction or dilation of the left ventricle.
- The primary *lesion* causing regurgitation seen on echocardiography is tethering of the valve leaflets.
- The primary resulting valve *dysfunction* is mitral regurgitation caused by restriction of leaflet motion, which occurs mainly in systole (Carpentier's type IIIB dysfunction).

Although annular dilation often coexists in chronic ischemic regurgitation, this is usually the secondary, rather

than primary, lesion. Ischemic mitral regurgitation with normal unrestricted leaflet motion (Carpentier type I dysfunction) can occur in the setting of a basal infarction, but such cases are infrequent. The infrequently encountered scenario where an infarcted papillary muscle elongates to cause leaflet prolapse (Carpentier type II dysfunction) is a rare form of ischemic mitral regurgitation and is considered briefly at the end of this chapter. When prolapse is seen in patients with ischemic heart disease, the more likely explanation is degenerative, rather than ischemic, etiology. A true type IIIA dysfunction (leaflet restriction in both systole and diastole) is not seen in ischemic mitral regurgitation. If a chronic type II or IIIB dysfunction is seen in a patient with ischemic heart disease, the surgeon must consider nonischemic etiologies: this distinction is important, because the therapy for ischemic mitral regurgitation—a downsized annuloplasty—can be potentially harmful if applied to patients with a type II or IIIA dysfunction if they are misclassified as having ischemic mitral regurgitation (Fig. 92-1).

	Type I	Type II	Type IIIB
			
Mechanism	Annular dilation	Leaflet prolapse	Leaflet restriction in systole
Prevalence	Common	Uncommon in acute settings due to early PCI, very rare in chronic scenarios	Most common
Common lesions	Circumferential annular dilation, posterior greater than anterior	Acute papillary muscle rupture (commonly the posterolateral papillary muscle due to single blood supply) or elongation of the papillary muscle due to chronic ischemia	Posterior leaflet restriction and tethering secondary to lateral displacement of the papillary muscles from ventricular remodeling
Surgical techniques	Restrictive ring annuloplasty	Mitral valve replacement Restrictive ring annuloplasty Papillary muscle reattachment (acute) Papillary muscle shortening (chronic) Leaflet resuspension with neochordae	Restrictive rigid ring annuloplasty Mitral valve replacement (severe) Leaflet patch augmentation Chordal cutting (secondary chords) Leaflet resuspension with neochordae (after resection of marginal chords in severe settings) Relocation of papillary muscles

FIGURE 92-1 ■ Carpentier's functional classification in ischemic mitral regurgitation (MR). Type I has normal leaflet motion, and MR is based on annular dilation. Type II dysfunction implies excess leaflet motion with the free edge of the leaflets above the annular plane during systole, which can occur because of papillary muscle rupture (acute infarction) or papillary muscle elongation (chronic). Type IIIB is the most common form of ischemic MR; it results from restricted leaflet motion during systole secondary apical and lateral papillary muscle displacement. *PCI*, Percutaneous coronary intervention.

The majority of patients with ischemic mitral regurgitation have so-called functional ischemic mitral regurgitation from IIIB dysfunction without any leaflet or subvalvular lesions (leaflet tethering occurring because of papillary muscle displacement). Although the term *functional* mitral regurgitation is commonly used to refer to mitral regurgitation without “organic” lesions of the mitral valve, its use should be discouraged, because it is an imprecise term and lacks the mechanistic and therapeutic correlates of the Carpentier functional classification. Furthermore, although it is often assumed that the valve apparatus is normal in functional regurgitation, pathologic studies have shown that these leaflets are thinned out with altered collagen composition compared with autopsy controls.⁴ Secondary mitral valve regurgitation is a more appropriate term because it differentiates mitral regurgitation due to secondary ventricular process, from that due to primary pathology of the valve leaflets or subvalvular apparatus.

A documented clinical history of a myocardial infarction (MI) is not mandatory for the diagnosis of ischemic mitral regurgitation. Although a prior MI is almost always present in these patients, it may be silent in many patients, especially in those with diabetes. In addition, the spectrum of ischemic mitral regurgitation likely includes a small number of patients with large areas of ischemic hibernating myocardium (without substantial infarction), causing papillary muscle displacement and type IIIB mitral regurgitation. However, for practical purposes, in this chapter we will assume (unless otherwise stated) that all patients have infarction-induced ventricular remodeling, as true ischemic mitral regurgitation without underlying infarction is not rare.

The optimal way to evaluate ischemic mitral regurgitation is by semiquantitative or quantitative assessment, preferably by transthoracic echocardiography performed while the patient is awake and not actively ischemic. General anesthesia and even the light sedation required for transesophageal echocardiography (TEE) can unload the ventricle and lead to underestimation of the degree of mitral regurgitation.⁵ In addition, the potential unloading effects of inotropes, vasodilators, and intra-aortic balloon pump can affect the degree of regurgitation. During the past two decades, state-of-the-art techniques for quantifying mitral regurgitation by echocardiography have emerged, and they are particularly useful for patients with ischemic regurgitation. The recommended method to measure the degree of the mitral regurgitation quantitatively is to calculate the regurgitant volume and the effective regurgitant orifice using the flow-convergence proximal isovelocity surface area method. These calculations along with evaluating for hemodynamic consequences of the regurgitation most accurately define the severity of the mitral regurgitation.⁶ The Mayo group has suggested that the thresholds for defining significant mitral regurgitation should be lower (regurgitant volume, ≥ 30 mL; effective regurgitant orifice area, ≥ 20 mm²) in secondary (functional) mitral regurgitation than in primary (organic) mitral regurgitation, given its effect on survival in this group.⁷ Cine ventriculography has been superseded by echocardiography for diagnosis and grading of ischemic mitral regurgitation. The absence of

mitral regurgitation on ventriculography should not be regarded as sufficient to exclude ischemic mitral regurgitation. This is increasingly important in the current era, as many interventionists have moved toward a low-volume injection technique for ventriculography, which is suboptimal for assessing mitral regurgitation.⁸

CLINICAL PRESENTATION

Ischemic mitral regurgitation has traditionally been characterized as acute or chronic. Rarely, some patients develop acute mitral regurgitation during bouts of ischemia; this type disappears with the revascularization or resolution of the ischemia and is not considered in this chapter. Acute mitral regurgitation as a result of papillary muscle rupture after acute myocardial infarction is discussed at the end of this chapter. The vast majority of patients with ischemic regurgitation have a specific propensity to mitral regurgitation because of effects of prior myocardial infarction, effects that are generally permanent and chronic unless they are ameliorated surgically. In many patients, ischemic mitral regurgitation is asymptomatic and is an incidental finding at echocardiography. When regurgitation is severe or long-standing, or when the degree of accompanying left ventricular dysfunction is severe, patients present with symptoms and signs of heart failure.

Patients with type IIIB ischemic mitral regurgitation typically present with one of two clinical scenarios (Fig. 92-2). The first scenario is a patient with symptomatic multivessel coronary artery disease, with or without associated congestive heart failure symptoms, who is referred for surgical or percutaneous revascularization and who is typically noted to have mild to moderate mitral regurgitation on preoperative or intraoperative imaging. The other scenario is a patient with moderate to severe mitral regurgitation and primarily congestive heart failure symptoms, who is referred for mitral valve surgery and who has significant coronary artery disease. Increasingly, patients in the latter group have undergone prior percutaneous or surgical revascularization. Associated coronary artery disease typically involves more than one vessel, but ischemic mitral regurgitation can also occur in the setting of single-vessel disease.

PATHOPHYSIOLOGY

Normal mitral valve function involves a complex, three-dimensional interaction among the leaflets, the annulus, the subvalvular apparatus, and the left ventricle. The mechanism by which myocardial ischemia and infarction perturb this carefully orchestrated process has been the focus of intensive laboratory investigation. Several groups have carefully analyzed the geometric mechanisms of ischemic mitral regurgitation in large animal models using biplane fluoroscopy, sonomicrometry, and two- and three-dimensional echocardiography. Although these studies have several limitations, they provide significant insight into the pathophysiology of ischemic mitral regurgitation and potential treatment modalities.

	Primarily Ischemia	Primarily Heart Failure
		
Mechanism	Posterior leaflet restriction	Leaflet restriction and annular dilation
Severity of MR	Mild to moderate	Moderate to severe
LV dysfunction	Mild to moderate	Moderate to severe
Ejection fraction (%)	30-50	15-40
Indication for surgery	Coronary artery disease	Congestive heart failure

FIGURE 92-2 ■ The two most common and relatively distinct clinical scenarios for patients with ischemic mitral regurgitation. Most patients have primarily ischemic symptoms, and they are noted on evaluation for coronary bypass surgery to have mild to moderate mitral regurgitation. A significant minority, however, primarily have symptoms of congestive heart failure and are noted on evaluation for mitral valve surgery to have significant coronary artery disease. Patients in the latter group tend to have worse left ventricular function. LV, Left ventricular; MR, mitral regurgitation.

The key pathophysiologic components of types I and IIIB ischemic mitral regurgitation include annular changes (dilation, distortion), subvalvular changes (papillary muscle displacement), and ventricular changes (dilation with increased sphericity, and wall motion abnormalities). Figure 92-3 provides an overview of how these components interact to result in poor leaflet coaptation, which is the final common pathway for all types of mitral regurgitation.

Specific Geometric Abnormalities

Annular

Although annular dilation is a common finding in clinical cases of chronic ischemic mitral regurgitation, the degree of dilation is often not severe and does not necessarily correlate with the degree of mitral regurgitation. Dilation of the annulus causes the leaflets to pull apart and hinders adequate leaflet coaptation. Although the posterior portion of the annulus is far more affected by ventricular or atrial enlargement, the anterior annulus has been shown to dilate as well.^{7,9-11} This concept has been demonstrated in both pathologic and imaging studies,^{11,12} which showed that although annular dilation is predominant in the region of the posterior commissure, it is often asymmetrically present throughout the annulus as well. Along with dilation, the annulus also flattens, losing its saddle shape, in ischemic mitral disease.^{10,12} The degree of annular dilation might not be a fundamental component of ischemic mitral regurgitation pathophysiology. Green and colleagues⁸

showed that in an acute sheep model, moderate degrees of annular dilation do not necessarily lead to ischemic mitral regurgitation. Timek and coworkers¹³ noted that the mild degrees of annular dilation that they observed during acute occlusion of the left anterior descending or distal left circumflex did not result in ischemic mitral regurgitation. This study, and several others from the same group, noted the critical role of the septolateral (SL) annular dimension in the pathophysiology and treatment of ischemic mitral regurgitation. The SL dimension—also referred to as the anteroposterior (AP) dimension—is the vertical or short axis of the annular ellipse that extends from the middle of the anterior annulus to the middle of the posterior annulus. The horizontal or long axis of the ellipse is referred to as the *commissure-commissure* (CC) dimension. Studies have shown that in the sheep acute ischemia model, an increase in mitral annular area causes mitral regurgitation only to the extent that it increases the SL dimension. Furthermore, these researchers also demonstrated the importance of the SL dimension by using a cinching device to diminish this dimension abolishing ischemic mitral regurgitation in sheep independent of overall annular circumference.^{14,15} Although the CC dimension does not usually increase significantly with ischemia,¹²⁻¹⁵ it has been shown to change proportionally with the change in the posterior annulus.^{9,11,16} This disproportionate posterior annular dilation accounts for the more significant increase in the SL dimension. In severe cases of ischemic mitral regurgitation, the SL dimension can approach the CC dimension, which results in a circular annulus rather than the normal ellipse.

FIGURE 92-3 ■ Pathophysiology of ischemic mitral regurgitation. The interaction among the left ventricle, the papillary muscles, the annulus, and the leaflets leads to poor leaflet coaptation as the final common pathway to mitral regurgitation. The posteroapical displacement of the papillary muscles away from each other (arrows) results in ischemic mitral regurgitation.

Subvalvular

Papillary muscle displacement also plays a critical role in the pathophysiology of ischemic mitral regurgitation. It is important to distinguish this from papillary muscle dysfunction (decreased or disordinated papillary muscle systolic shortening), which had previously been thought to be the primary mechanism for ischemic mitral regurgitation. In fact, papillary muscle dysfunction does not

necessarily result in ischemic mitral regurgitation. Timek and coworkers¹⁷ showed that the decreased shortening of one or both papillary muscles did not correlate with ischemic mitral regurgitation in the sheep. On the contrary, Messas and colleagues¹⁸ demonstrated a paradoxical decrease in ischemic mitral regurgitation with papillary muscle dysfunction.

The primary alteration in papillary muscle geometry leading to ischemic mitral regurgitation is papillary muscle

displacement. The pattern of displacement is actually fairly complex and cannot simply be described as apical tethering. The papillary muscle tips are displaced away from the midseptal (anterior) annulus (i.e., posterolaterally, apically, and away from each other). The tethering distance has been shown experimentally to correlate with the severity of ischemic mitral regurgitation.^{13,17,19} Experimental studies suggest that although displacement of both papillary muscles is probably necessary to induce ischemic mitral regurgitation, displacement of the posteromedial papillary muscle group usually predominates.

Left Ventricular

The initiating insult in ischemic mitral regurgitation is ventricular, specifically myocardial ischemia or infarction with remodeling that leads to regional annular and subvalvular distortion and ultimately poor leaflet coaptation. The independent contribution of global ventricular size and shape to the pathophysiology of ischemic mitral regurgitation is less clear. In an echocardiographic study of 102 patients, Kumanohoso and coworkers²⁰ showed that in comparison to those with anterior infarctions, patients with inferior infarctions had a higher incidence of ischemic mitral regurgitation despite less severe left ventricular dilation and dysfunction; this was directly attributed to more severe posteromedial papillary muscle tethering in the inferior infarction group. Experimental data, however, suggest that regional left ventricular dysfunction does not lead to ischemic mitral regurgitation without some degree of left ventricular dilation.

It appears that the left ventricular sphericity is more important than the actual ventricular volumes or ejection fraction in the pathophysiology of ischemic mitral regurgitation. Using three-dimensional echocardiography, several groups have shown that the mechanism of regurgitation differs according to the region of infarction. Watanabe and colleagues,²¹ for example, found that tethering was more localized and predominant in the medial posterior leaflet in patients with inferior infarction, compared with more widespread tethering of both leaflets in anterior infarction (Fig. 92-4).²¹ This observation confirms the critical role of regional ventricular geometry and function in the pathophysiology of ischemic mitral regurgitation and helps to explain why some patients with only mildly impaired global ventricular function have severe ischemic mitral regurgitation. Song and colleagues²² found that an inferior infarction coexisting with an anterior wall infarct led to a more severe regurgitation, independent of ventricular volume. These observations suggest that geometry of the valve apparatus may be a more important determinant of regurgitation than left ventricular volume or ejection fraction. It is possible, therefore, to have severe ischemic mitral regurgitation in the setting of relatively preserved ventricular function. Tethering is more symmetrical in patients with coexisting inferior and anterior infarction.²²

Leaflet Dysfunction

Papillary muscle tethering leads to apical tenting of the leaflets (restriction of the motion of the free margins of

the leaflets), which prevents the free margins of the leaflets from rising to the plane of the annulus to coapt with one another. Tethering of the secondary chordae can result in an *effet de mouette* deformation of the body of the leaflet, which further impairs coaptation. Leaflet tethering is typically asymmetric in ischemic mitral regurgitation. The posteromedial side of the valve (A3 and P3) has more pronounced restriction when compared with the anterolateral side (A1 and P1).^{23,24} Malcoaptation of the scallops of the posterior leaflet from papillary muscle tethering has also been implicated in the pathogenesis of ischemic mitral regurgitation.²⁵

THERAPEUTIC TARGETS IN ISCHEMIC MITRAL REGURGITATION

Being essentially a ventricular disease caused by coronary stenosis, with effects on the papillary muscle, cords, and leaflet coaptation, ischemic mitral regurgitation lends itself to several therapeutic targets.

Coronary Artery Disease

Coronary artery revascularization is necessary to recruit any hibernating myocardium and thus improve ventricular function. Revascularization can also help to limit future adverse remodeling resulting from continuing ischemia or new infarction. Revascularization alone is not, however, reliable as sole therapy for ischemic mitral regurgitation as the principal cause of the regurgitation, leaflet tethering caused by regional infarction, cannot generally be reversed by revascularization. Correcting ischemia alone has not been reliable at treating the valvular dysfunction, and leaves patients with residual regurgitation and higher rates of worsening regurgitation.^{26,27}

Mitral Annulus

The mitral annulus has been the principal target of surgical therapy for ischemic mitral regurgitation. Bolling and colleagues^{28,29} first popularized downsized annuloplasty to address secondary mitral regurgitation owing to cardiomyopathy in the 1990s. In this group's initial experience, flexible band annuloplasty was used; however, recent data support the use of complete rigid or semirigid downsized annuloplasty in ischemic disease.³⁰⁻³² The restrictive (or downsized or undersized) annuloplasty partly addresses the pathophysiologic derangements seen in ischemic mitral regurgitation. The annuloplasty corrects circumferential annular dilation, whereas downsizing aims to correct the septolateral displacement and thus reduces the tethering distance. Complete rigid or semirigid rings are preferred, as they ensure that the valve remains fixed in the new reduced SL dimension. Asymmetrical rings may be helpful in addressing the asymmetrical tenting seen in inferior infarction. Incomplete annuloplasty with flexible bands may not adequately reduce the SL dimension.

The differences in tethering between anterior and inferior infarctions raises question as to whether characteristics of annuloplasty rings should differ depending on

FIGURE 92-4 ■ Tenting and tethering of mitral leaflets into the left ventricle (LV) in patients with ischemic mitral regurgitation. Areas of greatest displacement are shown in *red*. For patients with inferior infarction, tenting of leaflet is more localized with less bulging. For patients with anterior infarction, mitral valve leaflets are widely tethered and bulge toward the LV. The tethered leaflet area is smaller in inferior than in anterior myocardial infarction. A, Anterior; L, lateral; LA, left atrium; M, medial; P, posterior. (Top panels adapted with permission from Watanabe N, Ogasawara Y, Yamaura Y, et al: Geometric differences of the mitral valve tenting between anterior and inferior myocardial infarction with significant ischemic mitral regurgitation: quantitation by novel software system with transthoracic real-time three-dimensional echocardiography. *J Am Soc Echocardiogr* 19:71–75, 2006.)

location of infarction. Lack of emphasis of the annuloplasty on areas of greatest tethering may be responsible for some recurrences after surgical repair. Better understanding of three-dimensional annular geometry can lead to the development of annuloplasty techniques that are tailored to the individual patient based on specific annular geometry and tenting distribution.

Subvalvular Apparatus

Subvalvular approaches aim to reduce leaflet tethering and thus allow better leaflet coaptation. Two broad approaches exist. First, tethering can be ameliorated by division of secondary chordae (Fig. 92-5).³³ Restrictive primary chords can also be divided and replaced with artificial chordae. Second, the tethering distance between the papillary muscle heads and the annular plane can be reduced by using external or internal devices. Several techniques have been developed that relocate the papillary muscles so that they are closer to the annulus (i.e., less displaced), thereby reducing the leaflet tethering.

FIGURE 92-5 ■ Distortion of the anterior leaflet resulting from tethering by secondary chordae, causing leaflet retraction and mitral regurgitation (MR). Division of these chordae results in better leaflet mobility and reduction in mitral regurgitation. PM, Papillary muscle. (Reprinted with permission from Messas E, Guerrero JL, Handschumacher MD, et al: Chordal cutting: a new therapeutic approach for ischemic mitral regurgitation. *Circulation* 104:1958–1963, 2001.)

FIGURE 92-6 ■ Patch placement and balloon inflation over infarct region (black) to reposition displaced papillary muscle (PM) toward anterior annulus and relieve tethering and mitral regurgitation (MR) under ultrasound guidance in a beating heart. AO, Aorta; LA, left atrium; LV, left ventricle. (Modified with permission from Hung J, Guerrero JL, Handschumacher MD, et al: Reverse ventricular remodeling reduces ischemic mitral regurgitation: echo-guided device application in the beating heart. *Circulation* 106:2594–2600, 2002.)

External devices designed to reduce tethering by displacing infarcted ventricle have also been investigated. Hung and colleagues^{34,35} used animal studies to evaluate an external device that works by displacing the infarcted ventricular wall that supported the tethered papillary muscle toward the mitral annulus. Use of this device should reduce tethering and resultant regurgitation (Fig. 92-6).^{34,35}

Leaflets

Because the leaflets are not directly involved in the causation of ischemic mitral regurgitation, there is limited scope for surgical intervention on the leaflets. Clefts tend to open up with leaflet tethering, and they may be closed at the time of mitral valve repair. The edge-to-edge leaflet technique has been proposed as an adjunct to annuloplasty,³⁶ but alone it is not as effective a treatment for ischemic mitral regurgitation compared with annuloplasty.³⁷ The edge-to-edge approach, however, is increasingly used with the percutaneous clip technique in patients who are not surgical candidates. There have been techniques for patch augmentation of both the anterior and posterior leaflet with acceptable early results; however, they may be technically challenging.³⁸

Left Ventricle

Operations to restore left ventricular geometry can reduce papillary muscle displacement and result in reduction of mitral regurgitation. This could be achieved by ventricular remodeling procedures (such as the Dor operation) or by localized plication of a lateral wall infarct. Approaches that halt the process of continued

ventricular remodeling can improve durability of ischemic mitral valve repair by limiting further papillary muscle displacement. For example, external ventricular restraint devices wrapped round the ventricle at the time of mitral valve repair have been shown to limit future dilation of the left ventricle³⁹; this eliminates one of the key pathophysiologic mechanisms for recurrent regurgitation after mitral annuloplasty (progressive ventricular remodeling). Injection of polymers into infarcted tissue has been explored experimentally by Hung and colleagues,⁴⁰ who demonstrated that polymer injection supported the infarcted ventricle and stabilized the papillary muscles, thereby resulting in acute reverse remodeling of the ventricle and reduction in papillary muscle displacement and decrease in mitral regurgitation. Finally, injection of myoblasts or stem cells into infarcted tissue is another potential use of the left ventricle as a target, as this could theoretically reduce mitral regurgitation by restoring ventricular function and therefore reducing tethering.⁴¹

The Coapsys device (Myocor, Inc., Maple Grove, MN) was an external compression device, placed without cardiopulmonary bypass, with an intracavitary cord that reshapes the left ventricle. By reshaping the ventricle, Coapsys compressed the mitral annulus and subvalvular apparatus and has been shown to decrease ischemic mitral regurgitation in animal studies.⁴² The RESTOR-MV trial randomized 149 patients with ischemic mitral regurgitation to CABG and conventional on-pump mitral valve repair or CABG with off-pump Coapsys implantation, and it found better survival and fewer adverse events in the Coapsys arm compared with standard surgical repair.⁴³ Unfortunately, the RESTOR-MV study was closed prematurely because of corporate financial issues, and the device did not achieve clinical approval, but the study is a useful demonstration that ventricular reshaping may be effective in ischemic mitral regurgitation.

PREOPERATIVE DECISION MAKING

Preoperative decision making in ischemic mitral regurgitation is complex and challenging. The clinical literature is often contradictory, making it difficult to synthesize and distill the information into concrete and practical clinical recommendations. Many factors must be considered in decision making, including the specific clinical scenario, the negative effects of ischemic mitral regurgitation on medium-term survival, the challenge of the intraoperative assessment of mitral regurgitation severity, the effects of coronary artery bypass grafting (CABG) alone on mitral regurgitation severity, the effects of CABG with or without mitral surgery on survival and late functional status, the additional operative risk of mitral valve surgery at the time of CABG, and the choice of valve repair versus replacement. We believe that the cumulative evidence and experience about these various issues are coalescing into a set of principles that can guide modern surgical decision making for the treatment of this disease (Fig. 92-7).

Decision Making in Specific Clinical Scenarios

Severe Ischemic Mitral Regurgitation with Congestive Heart Failure

Patients with severe mitral regurgitation, symptoms of congestive heart failure, or worsening left ventricular function are referred primarily for mitral valve surgery (as opposed to referred for coronary revascularization). The preoperative coronary angiogram typically shows significant coronary artery disease that may or may not have been symptomatic with angina. Patients may have undergone prior surgical or percutaneous revascularization. These patients typically have evidence of prior myocardial infarction and moderate or severe left ventricular

dysfunction. They can be viewed as ischemic cardiomyopathy with associated mitral regurgitation.

It must be stressed that in all these patients the initial therapy is guideline directed heart failure medical management. Medical therapy aims to maintain euvolemia and to reduce cardiac preload and afterload thereby optimizing cardiac performance. In many patients, medical management will result in reduction of severity of regurgitation, with varying degrees of symptom improvement.⁴⁴ Medical therapy includes maximally tolerated doses of diuretics, angiotensin converting enzyme inhibitors or angiotensin receptor antagonists, aldosterone antagonists, and beta blockers, especially carvedilol. Cardiac resynchronization therapy (CRT) with biventricular pacing should be used in patients with severe ischemic mitral regurgitation who show evidence of dyssynchrony.

Responders to CRT have been shown to have significant reduction in severity of secondary mitral regurgitation.⁴⁵⁻⁴⁷ Consideration for mitral valve surgery for severe ischemic regurgitation in the heart failure patient without primary indication for CABG should, therefore, be undertaken only after confirmation that medical therapy is optimal and CRT has been attempted or is not indicated. In general, surgical therapies are not considered, even if regurgitation remains severe on medical therapy, unless symptoms remain severe (New York Heart Association [NYHA] class III or IV). In selected low-risk patients, however, mitral valve surgery can be considered in NYHA II patients where the ventricle is not severely dysfunctional or remodeled with the hope that intervention can delay or prevent further negative remodeling. (Although there is no direct evidence to support this, randomized trials seem to show reverse left ventricular remodeling at 12 months in patients with moderate mitral regurgitation who undergo mitral valve repair.⁴⁸)

Patients who remain severely symptomatic (NYHA III or IV) despite medical therapy, and who have an ejection fraction over 30%, should be offered mitral valve surgery as the risk is acceptable (provided no major comorbidity) and patients can expect substantial improvement in symptoms. If the ejection fraction is particularly low (<30%), the decision to operate, in the absence of documented ischemia, is similar to the decision that needs to be made for patients with mitral regurgitation as a result of nonischemic cardiomyopathy. Patients with severe ischemic mitral regurgitation with symptoms of congestive heart failure or worsening left ventricular function (or both) can undergo combined mitral valve surgery and CABG as long as the expected operative morbidity and mortality is not prohibitive. For patients who survive and recover from surgery, the expected benefit of surgery would be better control of heart failure with likely improvement of symptoms. However, there is no clear evidence that life expectancy is improved by mitral valve repair in the setting of left ventricular dysfunction, and indeed some data suggest the contrary.⁴⁹ For this reason, advanced therapies for cardiac replacement (transplantation and left ventricular assist device implantation) have been used increasingly as options for treating ischemic mitral regurgitation in the severely dysfunctional and remodeled left ventricle (left ventricular end-diastolic diameter [LVEDD] > 65 mm), particularly where there is limited viability. Young patients with ischemic mitral regurgitation and severe left ventricular dysfunction, with NYHA class III or IV heart failure, should be screened to determine whether they meet indications and criteria for heart transplantation before undertaking mitral valve surgery. Some patients with advanced ischemic cardiomyopathy and ischemic mitral regurgitation, who are not candidates for transplantation, may be suitable for destination left ventricular assist device as an alternative to high risk mitral valve surgery.⁵⁰

An increasingly common scenario is severe mitral regurgitation seen in patients who have undergone prior CABG. Often, this regurgitation had not been addressed at the CABG procedure and has since progressed. These

patients present unique challenge because reoperation in the presence of patent coronary bypass grafts may increase operative risk. Thoughtful consideration for appropriate patient selection and operative strategy is warranted.⁵¹ Reoperative surgery to address ischemic mitral regurgitation is generally recommended only when quality of life is greatly impaired, despite optimal medical therapy (NYHA III or IV).

Mild or Moderate Ischemic Mitral Regurgitation in Patients Undergoing Coronary Artery Bypass Grafting

The other common clinical scenario is that of a patient with symptomatic coronary artery disease who is referred for CABG and who is noted to have mild or moderate mitral regurgitation on preoperative or intraoperative echocardiography. Although the patient may have shortness of breath—as an angina equivalent or symptoms or signs of congestive heart failure (sometimes recognized in retrospect)—myocardial ischemia (an acute coronary syndrome or chronic stable angina) usually dominates the clinical picture and is the primary indication for surgical intervention.

Mild mitral regurgitation usually does not need to be addressed at the time of revascularization.⁵²⁻⁵⁴ If there are indications that the mild regurgitation might not run a benign course (e.g., left ventricular enlargement, substantial infarction or nonviability, pulmonary hypertension, excessive leaflet tenting), then it should be managed as moderate regurgitation.

Although most surgeons agree that severe mitral regurgitation should be corrected at the time of CABG, irrespective of the presenting symptoms, the optimal management of moderate ischemic mitral regurgitation remains controversial. One school of thought favors an aggressive repair strategy for moderate regurgitation, and another is more conservative.

Those favoring a conservative approach argue as follows:

1. Revascularizing ischemic areas will improve regional wall motion and reduce the mitral regurgitation.^{55,56} This benefit of CABG on ischemic mitral regurgitation is seen most in patients who have viable myocardium in the area of revascularization and in patients who do not have dyssynchrony of the papillary muscles.⁵⁷
2. Some historical studies suggested that performing CABG alone does not have a negative effect on long-term survival or functional status, even if some residual mitral regurgitation persists.⁵⁸⁻⁶⁰
3. Mitral valve surgery adds significantly to the operative risk of CABG, with several historical and contemporary series reporting operative mortalities in excess of 10% with combined procedures.^{28,47,61-65}
4. Patients with moderate ischemic mitral regurgitation tend to have relatively small left atria, thereby making mitral valve exposure and repair more difficult.⁵³
5. Mitral valve replacement, if it is necessary, carries the potential burden of prosthesis-related morbidity.

Many other surgeons, however, advocate the more liberal application of mitral valve surgery in patients with moderate ischemic mitral regurgitation undergoing CABG, arguing the following:

1. Chronic ischemic mitral regurgitation is a dynamic condition that is highly dependent on preload and afterload. The preoperative echocardiogram merely represents a brief snapshot of the severity of mitral regurgitation at the time of the study. The fact that many patients with “moderate” mitral regurgitation, or less, present with symptoms of congestive heart failure or enlarged left atria suggests that they probably have frequent episodes of more severe mitral regurgitation.
2. CABG alone does not correct moderate ischemic mitral regurgitation in many patients, especially those with scarring from myocardial infarction and those with annular and ventricular dilation. Patients who do not have viable or hibernating myocardium are less likely to benefit from revascularization alone.^{26,66}
3. Significant residual ischemic mitral regurgitation can, according to several studies, result in late symptoms and decreased long-term survival (discussed later).
4. Mitral annuloplasty is usually technically feasible, and almost always corrects moderate ischemic mitral regurgitation, thereby making mitral valve replacement usually unnecessary (unless the specific preference of the surgeon).²⁶
5. The high operative mortality for combined mitral valve surgery and CABG reported in the literature is outdated and reflects a significant number of patients undergoing mitral valve replacement. Mitral valve repair in the modern era can be performed at the time of CABG, with an operative mortality as low as 2% to 4%.⁶⁷⁻⁷⁰
6. Leaving significant residual mitral regurgitation exposes the patient to a potential need for reoperative mitral valve surgery in the presence of patent coronary grafts, which carries substantial operative risk.⁵¹

Two randomized studies have evaluated the role for mitral valve annuloplasty in moderate ischemic mitral regurgitation. Fattouch and colleagues⁵³ randomized 102 patients to CABG alone or CABG with mitral annuloplasty. This study demonstrated an improvement in NYHA class and a reversal in left ventricular remodeling with the addition of mitral annuloplasty to CABG, but it did not demonstrate a survival advantage.⁵³ More recently the RIME investigators randomized 73 patients undergoing CABG with moderate ischemic mitral regurgitation to CABG alone or CABG and mitral annuloplasty. Compared with patients who had CABG alone, at 12 months patients who had a concurrent mitral valve annuloplasty had superior functional status measured by both the NYHA class and by peak oxygen consumption. Left ventricular reverse remodeling was also greater in patients who had concurrent mitral valve repair.⁴⁸

The summation of best available evidence is in favor of intervening on moderate degrees of regurgitation at the time of CABG,⁷¹ mainly because of benefit in

long-term functional status and left ventricular reverse remodeling. Concurrent mitral annuloplasty should therefore be considered in all patients having coronary artery bypass surgery who have documented moderate or greater mitral regurgitation, unless specific operative or patient-related factors suggest a need for a limited or expeditious operation, or if there is strong basis to believe the mitral regurgitation can reverse with revascularization alone (e.g., good global ventricular function with extensive viability and limited infarction). The recommended surgical intervention for moderate ischemic regurgitation is mitral annuloplasty, as this has been demonstrated in randomized trials to be effective (compared with CABG alone). The efficacy and safety of mitral valve replacement has not been evaluated in the setting of moderate mitral valve regurgitation.

OUTCOMES

There is a growing body of evidence about the negative effects of even modest degrees of ischemic mitral regurgitation on medium-term survival. The modest prognosis of patients with ischemic mitral regurgitation has been documented in a variety of clinical settings, with 3-year survival rates typically being in the range of 50% to 75%, depending on the severity of mitral regurgitation and other patient characteristics.

Effect of Ischemic Mitral Regurgitation on Survival after Myocardial Infarction

Several studies have documented the strong negative effect of mitral regurgitation on survival and occurrence of heart failure after acute myocardial infarction. In their analysis of a subgroup of 727 patients with acute myocardial infarction from the Survival and Ventricular Enlargement (SAVE) trial, Lamas and colleagues⁷² found that even mild mitral regurgitation at the time of presentation was an independent predictor of mortality (relative risk, 2.0), and that this effect could not be attributed to differences in left ventricular function. This finding was reaffirmed in a more recent multicenter retrospective review by Rossi and colleagues (Fig. 92-8).¹ Grigioni and coworkers⁷ found a direct correlation between survival and the severity of mitral regurgitation using quantitative echocardiography done within 6 weeks of myocardial infarction. Aronson and coworkers⁷³ showed similar results reporting on 1190 post-acute myocardial infarction patients with ischemic mitral regurgitation. Within 3 years, 30% of those with moderate or severe regurgitation were hospitalized for heart failure, compared with 5% for those without regurgitation (Fig. 92-9). The 3-year mortality was higher in those with moderate or severe regurgitation (35%) when compared to those without regurgitation (8%; hazard ratio, 5.5). Even mild regurgitation was a risk factor for medium-term mortality (hazard ratio, 2.0). The association between ischemic mitral regurgitation after myocardial infarction and increased mortality and heart failure symptoms is independent of left ventricular function.

(Adapted with permission from Rossi A, Dini FL, Faggiano P, et al: Independent prognostic value of functional mitral regurgitation in patients with heart failure. A quantitative analysis of 1256 patients with ischaemic and non-ischaemic dilated cardiomyopathy. *Heart* 97:1675–1680, 2011.)

Effect of Ischemic Mitral Regurgitation on Survival after Percutaneous Coronary Intervention

Pastorius and colleagues⁷⁴ examined long-term outcomes in 711 patients with moderate or greater mitral regurgitation at the time of percutaneous coronary intervention (PCI). They found that the presence of moderate or severe mitral regurgitation at that time was associated with a 5-year survival rate of 57%, compared with 97% for those without regurgitation (Fig. 92-10).⁷⁴

Even mild regurgitation was associated with reduced survival (5-year survival rate, 83%). These data corroborate the historical series from Ellis and colleagues,⁷⁵ who demonstrated that patients with moderate to severe mitral regurgitation and ejection fraction less than 40% had a 50% mortality at 3 years despite successful PCI. Kang and colleagues examined a prospective database of 185 patients with significant ischemic mitral regurgitation who underwent surgical CABG (with or without mitral annuloplasty) or PCI. This group showed a longer event-free survival with CABG and mitral annuloplasty compared with PCI (with no mitral valve intervention).⁷⁶ Other data from nonsurgical series also show that uncorrected regurgitation is associated with a poorer long-term survival.⁷⁷ PCI alone should therefore not be considered definitive therapy for patients needing coronary artery disease who have ischemic mitral regurgitation; in patients whose surgical risk is not excessive, the presence of mitral regurgitation should generally be an indication for surgical rather than percutaneous revascularization, provided the surgeon plans to address the mitral insufficiency.

Effect of Ischemic Mitral Regurgitation on Survival after Coronary Artery Bypass Grafting

Two historical studies from the 1980s suggested that preoperative mitral regurgitation is an independent risk

FIGURE 92-9 ■ Short-term effect of ischemic mitral regurgitation (MR) after myocardial infarction. **A**, Cumulative incidence of hospitalization for heart failure treatment. **B**, Cumulative incidence of death. Even patients with mild mitral regurgitation had worse outcomes. (Modified with permission from Aronson D, Goldsher N, Zukermann R, et al: Ischemic mitral regurgitation and risk of heart failure after myocardial infarction. *Arch Intern Med* 166:2362–2368, 2006.)

factor for late death in patients undergoing CABG.^{77,78} Uncorrected mitral regurgitation was an independent risk factor for late death, with a relative risk of 1.5 for each grade of mitral regurgitation. Subsequent studies have demonstrated that CABG alone does not seem to alter the natural history in patients with ischemic mitral regurgitation.^{26,79,80} The detrimental effect on survival of residual regurgitation after CABG, however, seems to be small if global left ventricular function is normal; therefore, it is not unreasonable to apply CABG alone in patients with good ventricular function and moderate

ischemic regurgitation.⁸¹ However, with depressed left ventricular function, studies consistently demonstrate worse survival and quality of life after CABG alone in patients with regurgitation and a severely depressed ventricular function.⁸²⁻⁸⁵ The best available evidence suggests that coronary artery bypass surgery alone does not eliminate the adverse effects of ischemic mitral regurgitation.⁷¹

Coronary Artery Bypass Grafting Alone or with Mitral Valve Intervention

Some have suggested^{85a} that ischemic mitral regurgitation is merely a marker for severe underlying ischemic heart disease and not a direct cause of late death. The body of evidence supporting a direct effect of ischemic mitral regurgitation on late survival is strong. It is particularly compelling because, in many studies, ischemic mitral regurgitation was a predictor of late mortality independent of the usual risk factors (e.g., age, ejection fraction, functional class), which argues against it simply being a confounding variable.

Although the strong effect of ischemic mitral regurgitation on survival supports mitral valve intervention in

many patients with ischemic mitral regurgitation, the decision about whether to intervene in a specific patient can be complex and must take into account multiple factors, including the specific clinical presentation, the presence of comorbid conditions, and the expected operative morbidity and mortality. For purposes of surgical decision making, it is useful to separately consider the two most common clinical scenarios, as noted earlier. Although the detrimental effects of ischemic mitral regurgitation are well known, it is not certain that eliminating mitral regurgitation at the time of CABG improves long-term survival.⁸¹

The severity of mitral regurgitation is of paramount importance when deciding whether to intervene in ischemic mitral regurgitation at the time of CABG. As noted earlier, the evaluation of mitral regurgitation severity should be based on a transthoracic echocardiogram performed in an awake patient. The downgrading of mitral regurgitation by intraoperative TEE has been well documented in the literature. Aklog and colleagues²⁶ showed that 90% of the patients with moderate mitral regurgitation on preoperative echocardiogram had their mitral regurgitation downgraded to mild or less at intraoperative TEE. In nearly one third of these patients, there was no detectable mitral regurgitation on intraoperative TEE (Fig. 92-11). Bach and coworkers⁵ compared preoperative TEE in patients under intravenous conscious sedation with intraoperative TEE in patients under general anesthesia; they noted a significant decrease in the size of the regurgitant jet in patients with “functional” mitral regurgitation, but not in those with flail leaflets. Grewal and colleagues⁸⁶ performed a similar study limited to patients with moderate or severe mitral regurgitation. Half of their patients were downgraded at least one grade, and this effect was again limited to those with functional mitral regurgitation.

The mechanism underlying this phenomenon is almost certainly the unloading effect of general anesthesia, which results in arterial vasodilation and venous vasodilation and decreases afterload and preload, respectively. Although the effects of afterload on mitral regurgitation are generally well recognized, the effects of preload are underappreciated and may in fact be more important. Increased preload results in left atrial, left ventricular, and annular dilation (which can increase leaflet separation)

FIGURE 92-10 ■ Influence of severity of mitral regurgitation (MR) on survival after percutaneous coronary revascularization. Presence of moderate or severe MR was associated with substantially poorer 5-year survival. (Reprinted with permission from Pastorius CA, Henry TD, Harris KM: Long-term outcomes of patients with mitral regurgitation undergoing percutaneous coronary intervention. *Am J Cardiol* 100:1218-1223, 2007.)

FIGURE 92-11 ■ The effect of coronary artery bypass grafting alone on patients with moderate (3+) ischemic mitral regurgitation (MR). Nearly 90% of patients were downgraded to 2+ MR or less on intraoperative (Intr-op) transesophageal echocardiography (TEE), which indicates that preoperative quantification of MR grade is critical. Although some patients had improvement in MR grade with coronary artery bypass grafting alone, 40% were left with 3 to 4+ MR and only in less than 10% was the MR completely corrected to 0 to 1+. Post-op, Postoperative; TTE, transthoracic echocardiography. (Adapted with permission from Aklog L, Filsoufi F, Flores KQ: Does coronary artery bypass grafting alone correct moderate ischemic mitral regurgitation? *Circulation* 104: 168-175, 2001.)

decrease leaflet coaptation and worsen mitral regurgitation severity. Grewal and coworkers⁸⁶ documented that decreased end-diastolic and end-systolic volumes in patients under general anesthesia support the role of altered loading conditions in this phenomenon.

Although these findings support careful preoperative echocardiography in patients scheduled for CABG with suspected mitral regurgitation, they do not diminish the importance and utility of intraoperative TEE in this setting.⁸⁷ On the contrary, TEE can provide important detailed anatomic information. In addition, intraoperative TEE with provocative testing to increase both preload and afterload may clarify the physiologic importance of the mitral regurgitation and assist with intraoperative decision making if the preoperative assessment is equivocal or unavailable. However, basing the decision not to intervene on (1) a downgraded intraoperative TEE without provocative testing or (2) the residual mitral regurgitation severity on TEE after the bypass graft is performed should be strongly discouraged.

Inadequacy of Coronary Artery Bypass Grafting Alone for Ischemic Mitral Regurgitation

Although earlier data were contradictory, with some studies suggesting that revascularization leads to resolution of ischemic mitral regurgitation^{88,89} and others suggesting that regurgitation usually persists or worsens,^{90,91} most authorities agree that resolution of mitral regurgitation does not predictably occur after coronary artery bypass surgery. Summation of the current literature seems to suggest that although CABG alone can sometimes decrease mitral regurgitation severity (particularly in patients with mild ischemic mitral regurgitation and poor left ventricular function), revascularization has an inconsistent and relatively weak effect on moderate ischemic mitral regurgitation, leaving many patients with moderate or greater mitral regurgitation.

A landmark study in 2001²⁶ was notable for challenging the notion that CABG alone was adequate for ischemic mitral regurgitation. One hundred and thirty-six patients with moderate ischemic mitral regurgitation underwent CABG alone. Among the 68 patients who underwent early postoperative transthoracic echocardiography (see Fig. 92-11), 40% showed no improvement and were left with moderate or severe residual mitral regurgitation. Approximately 50% of patients had some improvement and were left with mild mitral regurgitation. Only a few remaining patients (<10%) had significant improvement, with no more than trace (0 to 1+) mitral regurgitation. The study concluded that CABG alone was not the optimal therapy for many patients with moderate ischemic mitral regurgitation. This study was more recently corroborated by two randomized control trials.^{10,53}

Although CABG alone might not correct ischemic mitral regurgitation, skeptics have argued that residual mitral regurgitation after CABG alone does not itself have an adverse effect on late functional status or survival. The Emory group followed a cohort of 58 patients undergoing CABG alone for moderate mitral regurgita-

tion between 1977 and 1983, and in their most recent update,⁶⁰ 5- and 10-year actuarial survival rates were nearly identical to those of a control group of patients without preoperative mitral regurgitation and who underwent CABG during the same time period. Their patients, however, differ from the patients with typical ischemic mitral regurgitation in most modern series. Specifically, they were relatively young (mean age, 63 years) with normal left ventricular function (mean ejection fraction, 53%) and little or no congestive heart failure (10% in NYHA class III or IV), and nearly a quarter of their patients had nonischemic etiologies such as leaflet prolapse and rheumatic heart disease. However, two large studies from the same era found that mitral regurgitation was an independent risk factor for late death in patients undergoing CABG.^{77,78} The authors recommended the more liberal application of concomitant mitral valve repair for moderate and severe mitral regurgitation.

There is limited information in the literature about the late functional status of patients undergoing CABG alone for moderate ischemic mitral regurgitation. The Emory study reported a trend toward more class III and IV angina (29% vs. 6%) and congestive heart failure (14% vs. 6%) as compared with the case-matched controls. These findings suggest that even if the significant rate of residual mitral regurgitation after CABG alone does not result in decreased long-term survival, it can adversely affect long-term functional status and quality of life. Concomitant mitral valve repair may therefore be justified (if it can be performed with relatively low operative risk) to improve long-term functional status independent of effect on survival.

The inadequacy of CABG alone is further supported by various epidemiologic studies that demonstrate that revascularization by either PCI or CABG is still associated with persistent regurgitation and reduced medium-term survival despite revascularization.^{7,26,77-80}

Effect of Mitral Valve Surgery on Natural History of Ischemic Mitral Regurgitation

There are no randomized trials comparing CABG alone to CABG and mitral valve surgery in the context of severe ischemic mitral regurgitation (the only trials conducted have been for moderate regurgitation). Studies that have attempted direct comparison of these groups are limited, because undocumented patient and surgical factors, or surgeon preferences and bias, often influence the decision to repair or not repair these valves, making it difficult to directly compare groups.⁹² The Cleveland group, using propensity matching to partly balance for selection bias, demonstrated equivalent results with CABG alone compared with CABG and mitral valve repair⁸¹; that study is, however, of limited applicability to current patient cohorts, as many of the surgical procedures undertaken (notably, use of pericardium and flexible bands) have since been superseded and are no longer recommended by most authorities for treatment of ischemic mitral regurgitation. There are numerous reports in the literature on the outcome of mitral valve repair for ischemic mitral regurgitation. These reports are mixed, with some

suggesting it is an effective therapy and others suggesting otherwise. Some reports from the 2000s suggest that mitral valve repair is ineffective for ischemic regurgitation, because many patients were observed to have recurrent regurgitation early after surgery.⁹³⁻⁹⁵ There are, however, flaws in these studies, which we have discussed elsewhere.³ Notably, the surgical techniques were inconsistent, inadequate, or historical; the follow-up was often incomplete; cohorts were heterogeneous; and the methodologic and statistical approaches were sometimes inappropriate (Table 92-1). These limitations make it impossible to draw reliable conclusions from these studies about the efficacy of mitral valve annuloplasty.

Recent papers continue to add to the controversy over whether mitral valve repair is effective for ischemic mitral regurgitation. Although several studies have reported disappointing outcomes with mitral valve repair,⁹⁶ most studies remain limited by critical flaws, thus preventing robust extrapolation.⁹⁷ Common to those studies suggesting ineffectiveness of mitral valve repair is the absence of systematic use of a restrictive annuloplasty using a complete rigid or semirigid ring, as varying proportions of patients in these studies received incomplete flexible rings or pericardium for annuloplasty, which are not recommended for ischemic mitral regurgitation. These flaws can be observed in most studies in the current surgical literature that demonstrate lack of effectiveness of

annuloplasty, compared with CABG, in ischemic mitral regurgitation.⁹⁷

Excellent Midterm Results with Downsized Annuloplasty

The Leiden group has been notable in their work on systematic downsized annuloplasty to treat functional mitral regurgitation.⁶⁶ In a report of 100 consecutive patients who underwent a mitral valve repair for ischemic mitral regurgitation using a semirigid Carpentier Edwards Physio ring annuloplasty (Edwards Lifesciences LLC, Irvine, CA) downsized by two sizes,⁹⁸ echocardiography at mean follow-up of 4.3 years showed that 85% had zero or mild regurgitation, and the 5-year survival rate was 71%. They observed superior outcomes when the preoperative LVEDD was 65 mm or less (Fig. 92-12). This group has also observed sustained reduction in left ventricular end-diastolic diameter at midterm follow-up for patients with LVEDD less than 65 mm at the time of repair.⁹⁹

The Leiden experience^{66,98} has several notable factors that differentiate it from the reports that suggest poor or limited efficacy of annuloplasty for ischemic mitral regurgitation.^{62,65,81,93-96} The immediate postsurgical results suggest that the mitral valve repair was effective because no patients had residual regurgitation leaving the operating room; the patients were all operated in a more recent

TABLE 92-1 Recent Studies Suggesting Limited Efficacy of Restrictive Annuloplasty in Ischemic Mitral Regurgitation

Reference	Main Result	Conclusion	Limitations
Crabtree and colleagues ⁶²	52% survival at 5 years, 28% moderate or severe MR at latest TTE	Questions the benefit of adding annuloplasty to CABG	Use of inadequate technique: 44% of patients received an incomplete (posterior) annuloplasty with a flexible band. Such bands have limited efficacy, as they do not address tethering and dilation in anterior annulus
Gelsomino and colleagues ⁹⁵	Reverse remodeling seen in only 41% of patients	Annuloplasty + CABG is ineffective in a large percentage of patients	Echo follow-up available for only 57% Suboptimal early results: 7% repair failure or residual MR rate Limited revascularization approach: Average of two bypasses per patient suggests incomplete revascularization
Mihaljevic and colleagues ⁸¹	CABG + annuloplasty did not improve long-term functional status or survival compared with CABG alone	Annuloplasty is insufficient to improve long-term clinical outcomes	Historical cohort: Patient inclusion began in 1991, so does not fully reflect recent advances in surgery (e.g., downsized annuloplasty); the current therapy for ischemic regurgitation became routine only in the late 1990s. Unusually high survival rate in CABG-only group: 5-yr survival of 75% not typical in most surgical series Ineffective technique: 15% of propensity-matched patients had annuloplasty with pericardial strips, a technique shown to be ineffective with unacceptably high recurrent MR rate Inadequate technique: 59% of patients received flexible posterior bands, which do not address anterior tethering and dilation.

FIGURE 92-12 ■ Actuarial survival rates for two different preoperative left ventricular end-diastolic diameter (LVEDD) cohorts after restrictive annuloplasty, comparing LVEDD greater than 65 mm and LVEDD 65 mm or less (hazard ratio, 3.4; 95% confidence interval, 1.5-7.4; $P = 0.002$). (Adapted with permission from Braun J, van de Veire NR, Klautz RJ, et al: Restrictive mitral annuloplasty cures ischemic mitral regurgitation and heart failure. *Ann Thorac Surg* 85:430-436, 2008.)

era (2000 or after); the annuloplasty was standardized across all patients and always complete, semirigid, and downsized; and echocardiographic follow-up was systematic. Another more contemporary report from Gazoni and colleagues⁶⁹ supports the findings of the Leiden group: in a series of 105 ischemic repairs, a 5-year survival of 84% was observed with a low (6.3%) incidence of recurrent regurgitation on medium-term (>12 months) echocardiography. Geidel and colleagues,⁷⁰ also using predominantly remodeling annuloplasty, were also able to demonstrate excellent medium-term results with restrictive annuloplasty.

Although no good randomized clinical trial has been performed that demonstrates the superiority of complete rigid ring or semirigid annuloplasty over flexible annuloplasty, there is mounting evidence showing significantly improved rates of recurrent regurgitation with minimal incidence of postoperative mitral stenosis in patients receiving complete rings.^{31,32}

Residual Mitral Regurgitation after Ischemic Mitral Valve Repair

Surgical Techniques and Incidence of Residual Mitral Regurgitation

Surgical technique and patient selection are probably the principal determinants of residual mitral regurgitation. With appropriate technique, residual regurgitation (defined as regurgitation other than trivial or mild on leaving the operating room or on predischARGE echocardiography) should be infrequent (<5%) after ischemic mitral repair. Clinical and experimental evidence suggest that any technique other than a complete rigid or semirigid ring is prone to a high incidence of residual regurgitation.⁹³

Suture annuloplasty has a particularly high incidence of residual mitral regurgitation when applied to patients with ischemic mitral regurgitation. Hausmann and coworkers⁶³ reported a 28% incidence of residual mitral regurgitation of at least 2+ with this technique. Von Oppell and colleagues⁴⁷ had a 13% incidence of moderate mitral regurgitation in a series in which most patients underwent suture annuloplasty. Czer and coworkers¹⁰⁰ found that suture annuloplasty failed to decrease mitral regurgitation severity by two grades in 33% of patients. Grossi and coworkers¹⁰¹ noted a significant survival benefit (hazard ratio, 0.29) for ring annuloplasty over suture annuloplasty, with a 5-year survival rate of 74.3% compared with 52.7%, respectively ($P = 0.06$). Although appropriately applied suture annuloplasty can eliminate mitral regurgitation in the short term and it preserves annular contraction, as is well demonstrated in animal studies,^{102,103} these repairs do not seem to be consistently effective and durable in the clinical setting.⁹⁹ Though few groups continue to experience satisfactory results with suture annuloplasty,¹⁰⁴ most surgeons have abandoned the suture method in favor of the more predictable results with ring annuloplasty.

Annuloplasty using a pericardial band has also been shown to be less effective than prosthetic ring annuloplasty, with more than 30% of patients having persisting grade 3+ or 4+ mitral regurgitation after repair.⁹³ The prosthetic ring or band annuloplasty has better results than other techniques, with many groups reporting residual regurgitation rates of less than 10%.

Partial posterior ring annuloplasty has been used in the past because of ease of implantation, especially when there is difficulty exposing the anterior annulus. However, most surgeons prefer a complete ring annuloplasty to address the anterior annulus, which has been shown to dilate in functional mitral regurgitation.¹¹ The initial studies reported by Bolling and colleagues²⁹ described excellent results with a downsized annuloplasty using a flexible ring in ischemic mitral regurgitation. Since those studies, an advantage has been shown using rigid or semirigid ring annuloplasty in this disease process. Tahta and coworkers⁹⁵ showed a 29% (2+ regurgitation or greater) recurrence of mitral regurgitation in 100 patients who underwent CABG and annuloplasty with a flexible Duran ring at 3-year follow-up. This was a considerably higher rate than that seen in series of rigid or semirigid annuloplasty.⁹⁸ Silberman and colleagues³¹ retrospectively compared flexible to semirigid annuloplasty systems. They showed improved hemodynamics, greater reduction in recurrent mitral regurgitation, and a decreased incidence of recurrent regurgitation with the semirigid annuloplasty technique.³¹ Kwon and colleagues³⁰ retrospectively showed an advantage with complete ring annuloplasty when compared with a partial annuloplasty in functional mitral regurgitation (majority of patients were ischemic). Nonflexible rings have been shown to provide better durability in functional disease.³²

Downsizing of prosthetic annuloplasty seems vital in achieving a zero or near zero rate of residual regurgitation. Bolling and colleagues²⁹ were the first to popularize the downsized annuloplasty. They achieved no residual mitral regurgitation in 46 patients undergoing an

annuloplasty alone at the time of CABG, despite using a flexible rather than a rigid annuloplasty. The Leiden group more recently demonstrated zero residual regurgitation rates with the downsized annuloplasty.⁶⁶

Possible Mechanisms of Residual Mitral Regurgitation

A flexible reduction annuloplasty device, such as the Cosgrove-Edwards (Edwards Lifesciences) band or the Duran (Medtronic, Minneapolis, MN) ring, seeks to improve leaflet coaptation by simply decreasing the annular circumference, which indirectly brings the leaflets together. A rigid or semirigid remodeling annuloplasty ring such as the Carpentier-Edwards Classic (Edwards Lifesciences) is designed not only to decrease the annular circumference but, in addition, remodel the systolic annulus back into a kidney shape. This should, in theory, decrease the SL dimension to a greater degree than would a flexible annuloplasty of the same size. This should, in turn, lead to a larger surface of coaptation and less mitral regurgitation. The difference between reduction and remodeling annuloplasty in patients with type IIIB mitral regurgitation is illustrated in Figure 92-13.

Inadequate downsizing or inappropriate sizing may be a potential explanation for residual regurgitation. A true

sized annuloplasty will diminish the mitral regurgitation, but the zone of coaptation might not be sufficient. It has been suggested that the durability of repair is less if the length of the coaptation zone is less than 8 mm. Calafiore and coworkers¹⁰⁵ and Yiu and coworkers¹⁰⁶ have provided evidence that the coaptation depth is important in patients with “functional” mitral regurgitation in the setting of nonischemic cardiomyopathy. Nagasaki and colleagues¹⁰⁷ compared ischemic and nonischemic cardiomyopathy and found that the coaptation depth was the main determinant of severity of regurgitation in the ischemic patients. With appropriate downsizing, the AP dimension is aggressively reduced to bring the restricted posterior leaflet close enough to the anterior leaflet to allow adequate coaptation. Series in which there has been systematic downsizing, especially with a rigid or semirigid ring, report better freedom from recurrent or residual regurgitation compared with series in which there has not been significant downsizing (Fig. 92-14).

Patient Factors Associated with Residual Regurgitation

Patient factors can predispose to residual regurgitation. There are several identified echocardiographic predictors of failure of repair (Box 92-1); these are mainly markers

FIGURE 92-13 ■ Unrepaired annulus (A) of a patient with type IIIB mitral regurgitation leading to leaflet tethering. D, Flexible partial-reduction annuloplasty band (B) can reliably reduce the posterior annulus to a specific size, but the degree to which it remodels the annulus and restores coaptation depends on the relative degrees of annular dilation and posterior leaflet restriction. E, Downsized remodeling annuloplasty ring (C) predictably fixes the anteroposterior dimension, which should result in a larger surface of coaptation (F).

FIGURE 92-14 ■ Incidence of recurrent $\geq 2+$ mitral regurgitation (MR) reported in the literature as a function of time after mitral valve annuloplasty.

BOX 92-1 Predictors of Recurrent Mitral Regurgitation after Mitral Valve Annuloplasty in Patients with Ischemic Mitral Regurgitation

TTE

Indicators of Severe Mitral Valve Tenting

- Systolic tenting area $\geq 2.5 \text{ cm}^2$
- Systolic tenting height $\geq 10 \text{ mm}$
- Posterior mitral leaflet angle ≥ 54 degrees
- Distal anterior mitral leaflet angle ≥ 19 degrees
- Posterior mitral leaflet angle ≥ 45 degrees
- Anterior mitral leaflet tethering angle ≥ 39.5 degrees
- MR jet direction: central or complex

Indicators of Advanced LV Remodeling

- LVESD $> 51 \text{ mm}$
- LVEDD $> 65 \text{ mm}$
- LVESV $\geq 145 \text{ mL}$
- Interpapillary muscle distance $> 20 \text{ mm}$
- Systolic sphericity index ≥ 0.7

Other

- Myocardial performance index ≥ 0.9
- Wall motion score index ≥ 1.5
- Diastolic LV function: restrictive filling

TEE

- Mitral annular diameter in diastole $> 3.7 \text{ cm}$
- Tethering area $> 1.6 \text{ cm}^2$
- MR severity > 3.5

SURGICAL

- Use of flexible ring
- Use of incomplete ring
- Inadequate ring sizing
- Length of leaflet coaptation $< 1.9 \text{ mm/m}^2$ or $< 8 \text{ mm}$
- Residual mitral regurgitation

POSTOPERATIVE

- Absence of early LV remodeling (decrease of LVESV $< 15\%$)
- Residual MR at discharge

LV, Left ventricle; LVEDD, left ventricle end-diastolic diameter; LVESD, left ventricle end-systolic diameter; LVESV, left ventricle end-systolic volume; MR, mitral regurgitation; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

Adapted from Crestanello JA: Surgical approach to mitral regurgitation in chronic heart failure: when is it an option? *Curr Heart Fail Rep* 9:40–50, 2012.

of extreme left ventricular remodeling and/or severe valve tethering.¹⁰⁸ A missed primary lesion can be the cause of residual regurgitation,¹⁰⁹ such as regurgitation through a prominent cleft that is exaggerated after adequate loading of the ventricle is achieved.¹¹⁰ This can be avoided by assuring an adequate zone of coaptation and by closing significant clefts.¹¹¹ Occasionally, residual regurgitation could be due to a coexisting nonischemic etiology, such as degenerative prolapse, calcification, or rheumatic changes.

Incremental Operative Risk of Mitral Valve Surgery (versus Coronary Artery Bypass Grafting Alone) in Ischemic Mitral Regurgitation

A critical piece of information that a surgeon must consider when contemplating concomitant mitral valve surgery for ischemic mitral regurgitation is the additive operative risk of intervening on the mitral valve. A low operative risk would justify a more aggressive approach, given the potential benefit on late outcomes that we have outlined. A high incremental risk would justify a more conservative approach, although it should be kept in mind that the benefit of mitral valve surgery may also be greatest in certain high-risk patient groups (e.g., NYHA classes III and IV heart failure). Leaving the operating room with significant mitral regurgitation can also be most detrimental to the postoperative course of the sicker high-risk patients with poor ventricular function and more comorbidity.

The operative risk for patients undergoing surgery for ischemic mitral regurgitation depends on a number of preoperative factors, most notably age, left ventricular dysfunction, and other cardiac surgical risk factors. Because patient characteristics vary widely among different clinical series, it is difficult to precisely quantify the additional operative risk of mitral valve surgery in a given patient with ischemic mitral regurgitation. Extrapolation from the clinical literature is also challenging, because uniform definitions of ischemic mitral regurgitation have not been used. Some studies include patients with ruptured papillary muscles or with chronic ischemic type II dysfunction, and even degenerative patients with incidental coronary artery disease in cohorts of ischemic mitral regurgitation.

Several historical series have, however, suggested that the presence of ischemic mitral regurgitation does appear to increase the operative risk of CABG alone.* The 3% to 12% mortality rates seen in these studies are higher than those of most contemporary CABG series (generally around 2%).

Although the reported operative mortality for mitral valve replacement at the time of CABG has remained relatively high, the outcomes for mitral valve repair appear to be improving over time, with more recent series reporting operative mortalities of less than 5%.^{67,69,112}

Mitral Valve Repair versus Replacement for Ischemic Mitral Regurgitation

Although mitral valve repair for ischemic mitral regurgitation carries some of the same obvious benefits over replacement that it does for other etiologies (avoiding prosthetic valve-related complications), the higher incidence of repair failure and lower event-free survival with ischemic disease (compared with degenerative and rheumatic cohorts), makes the benefit of repair over replacement less certain when compared with other etiologies.

*References 26, 55, 56, 89, 91, 92.

For this reason, several authors have questioned whether the more effective (in terms of cure of regurgitation) valve replacement should be the preferred option to mitral valve repair (with less certainty of stable long-term freedom from regurgitation), with the hypothesis that the benefits of a more durable fix for the regurgitation would outweigh the incremental risks of a valve replacement. Although valve replacement would yield more durable elimination of regurgitation, there is a higher risk of surgical mortality, late mortality, valve-related morbidity and mortality, and a lesser degree of reverse remodeling with valve replacement.¹¹³⁻¹¹⁵ Historically, the poor results of mitral valve replacement in the setting of advanced ischemic or nonischemic cardiomyopathy led to most surgeons abandoning valve replacement in this setting during the 1980s and 1990s. However, some surgeons later adopted mitral valve replacement, with complete chordal and leaflet preservation, as primary therapy for ischemic mitral regurgitation and reported early results similar to those seen with mitral valve repair.¹¹⁶

Several observational studies have addressed this dilemma. Gillinov and colleagues¹¹⁴ retrospectively analyzed outcomes after repair (remodeling annuloplasty was used in one third of patients, with the remainder receiving a partial flexible band or pericardium for annuloplasty) or replacement in patients with ischemic mitral regurgitation and found that although there was a survival benefit seen with valve repair (5-year survival repair 58% versus 36% for replacement), the highest-risk patients had similar survival rates. The benefit of repair over replacement was diminished in patients with lateral wall motion abnormalities and complex regurgitant jets. This suggested that in some high-risk patients with ischemic mitral regurgitation, a chordal-sparing valve replacement may be an acceptable alternative to repair. Grossi and coworkers¹¹⁷ found better early survival (odds ratio, 0.43), complication-free late survival (odds ratio, 0.5), and a trend toward better overall survival with valve repair.

Most recently, the Cardiothoracic Surgical Trials Network¹¹⁸ conducted a multicenter randomized study enrolling patients with severe ischemic mitral regurgitation to undergo mitral valve annuloplasty or valve replacement (Fig. 92-15). The randomized trial identified no difference in survival, left ventricular remodeling, or quality of life measures at 12 months. However, the group did see a higher occurrence of recurrent mitral regurgitation at 12 months (32.6% with repair, 2.3% with replacement). The authors, however, do not explicitly recommend either valve replacement or repair as the preferred therapy for ischemic regurgitation, and they note that the higher incidence of regurgitation with repair needs to be balanced against (long-term) adverse effects of a prosthetic valve (these were not analyzed in this study). The high rate of recurrence in the repair group is concerning, however, and further analysis will be required to understand the reasons behind such high failure rate (relative to some contemporary series which show much lower early recurrence rate) and to identify surgical and patient predictors of failure.

In another recent analysis, Lorusso and colleagues¹¹⁹ reported results of the Italian, multicenter, retrospective study of ischemic mitral regurgitation patients with a

FIGURE 92-15 ■ Rates of New York Heart Association (NYHA) class and death at baseline, 6 months, and 12 months. MV, Mitral valve. (Adapted with permission from Acker MA, Parides MK, Perrault LP: Mitral-valve repair versus replacement for severe ischemic mitral regurgitation. *N Engl J Med* 370:23–32, 2014.)

reduced ejection fraction. This high risk population was shown to have no benefit with mitral valve repair and, once again, a higher rate of recurrent regurgitation with repair.¹¹⁹

The majority of mitral valve replacements have traditionally been biologic because of the perceived short life expectancy with these patients.¹²⁰ As medical therapy has improved, biologic valve degeneration has been seen with patients who initially underwent an operation for ischemic mitral regurgitation. These high-risk patients may then require a reoperation or reintervention that would entail a higher operative risk than the initial operation.

The decision regarding mitral valve repair or replacement is best made in consideration of individual patient characteristics. Patients with ischemic regurgitation who have echocardiographic findings that increase the risk of recurrent mitral regurgitation or repair failure should be considered for mitral valve replacement. Patients with moderate regurgitation and those with severe regurgitation who have minimal predictors of failure (see Box 92-1) are likely to have durable results with a repair. Patients who have unsatisfactory results with repair on intraoperative TEE should be considered for a second bypass run and valve replacement, because it is well documented that patients with residual regurgitation have poor long-term outcomes.

Overall Recommendations for Ischemic Mitral Regurgitation during Coronary Artery Bypass Grafting

Although most surgeons agree that severe mitral regurgitation should be corrected at the time of CABG, there is no consensus on the management of mild to moderate ischemic mitral regurgitation at the time of CABG. A preponderance of evidence seems to support a

more liberal application of concomitant mitral valve surgery, which can be summarized in the following recommendations.

1. All patients referred for CABG with suspected ischemic mitral regurgitation should undergo careful preoperative transthoracic echocardiography, preferably with quantitative assessment of mitral regurgitation severity while they are not actively ischemic. Those without complete preoperative assessment should undergo careful intraoperative TEE assessment of their mitral valves to determine whether there is an anatomic substrate for ischemic mitral regurgitation. If intraoperative echocardiography shows less mitral regurgitation than expected on the basis of the clinical picture, the patient should receive provocative testing of the degree of mitral regurgitation.
2. Patients with severe ischemic mitral regurgitation should undergo concomitant mitral valve repair. Mitral valve replacement is a reasonable option depending on surgeon preference and expected likelihood of repair durability.
3. Patients with moderate ischemic mitral regurgitation should undergo concomitant mitral valve repair unless preoperative or intraoperative factors suggest that the additional operative morbidity and mortality would be prohibitive (e.g., extensive mitral annular calcification or a strong indication for performing the CABG off pump, such as a heavily diseased ascending aorta).
4. Patients with mild ischemic mitral regurgitation may undergo concomitant mitral valve repair (with caveat similar to that for moderate regurgitation) if history or evaluation is suggestive of periods of greater severity of mitral regurgitation than has been documented. Pointers that suggest the mitral regurgitation may be more severe than appreciated include symptoms of congestive heart failure, enlarged left atrium, enlarged or dysfunctional left ventricle, pulmonary hypertension, and atrial fibrillation. In addition, anatomic findings present on intraoperative TEE should also be considered (e.g., minimal surface of coaptation, severe leaflet tenting coaptation depth, significant annular dilation).

SURGICAL PRINCIPLES

Basic Principles

The basic principles of mitral valve repair for ischemic mitral regurgitation are not fundamentally different from those for degenerative disease. A successful outcome depends on the following:

- Careful review of the preoperative echocardiogram, with particular attention paid to the mechanism of mitral regurgitation, the direction of the mitral regurgitation jets, and specific anatomic abnormalities (e.g., calcification, thickening)
- Good visualization of the entire valve
- Careful segmental valve analysis to confirm the mechanism of mitral regurgitation

- Meticulous suture placement and ring sizing
- Consideration of adjunctive technique, as appropriate

Annuloplasty: Underlying Principles

The significant effects of even mild degrees of ischemic mitral regurgitation on survival should challenge surgeons to make every effort to minimize residual mitral regurgitation after mitral annuloplasty. Careful consideration should be given to choice of annuloplasty method.

The literature does not, in our opinion, support a role for suture or pericardial annuloplasty in this disease. As mentioned previously, the rates of residual mitral regurgitation for these techniques are relatively high. Although the three-dimensional dynamic nature of mitral annulus and its contribution to ventricular function have been well documented, it is unclear what role this plays in pathologic conditions such as ischemic mitral regurgitation. Some laboratory studies suggest that planar fixation of the annulus with a nonflexible ring impairs left ventricular function, whereas others dispute this.²⁸ We suspect, however, that there is a critical role for annular remodeling, specifically in the SL (or AP) dimension in patients with Carpentier-type IIIB dysfunction. As described earlier, a large body of data has been accumulated from several laboratories that describe the mechanisms that contribute to ischemic mitral regurgitation. Several of these studies emphasize the importance of the increased SL dimension in pathophysiology of ischemic mitral regurgitation. It seems, therefore, that the need to remodel the annulus (with a remodeling rigid or semi-rigid ring) far outweighs any benefit of preserving annular motion.

As illustrated in [Figure 92-16](#), a reduction annuloplasty will, to some degree, decrease the SL dimension, improve leaflet coaptation, and correct mitral regurgitation. The extent to which it accomplishes this, however, probably depends on whether the annular dilation or posterior leaflet restriction is the dominant mechanism of mitral regurgitation. If there is predominant annular dilation (type I dysfunction), a flexible band is not an unreasonable option. However, for most patients, where valve tethering is dominant, a complete downsized rigid or semirigid ring should be used for ischemic mitral valve repair.

Asymmetric rings designed specifically for the treatment of ischemic mitral regurgitation can be utilized. For example, the Carpentier-McCarthy-Adams IMR ETlogix ring (Edwards Lifesciences, Irvine CA; see [Fig. 92-16](#)) has a decreased AP diameter (i.e., is pre-downsized); and is asymmetrical, with a narrower dimension at P2-P3, and it has a slight dip at P2-P3 to accommodate the greater posterior leaflet restriction in this region.¹²¹

Valve Exposure

The most common approach to patients with ischemic mitral regurgitation is a full sternotomy with cannulation of the ascending aorta and both venae cava. After completion of bypass grafting, as appropriate, the mitral valve

FIGURE 92-16 ■ Symmetrical (A and B) and asymmetrical (C and D) patterns of ischemic mitral regurgitation. Note the difference of coaptation lines (white arrows) after remodeling annuloplasty.

can be exposed either via the interatrial groove or trans-septally. Patients with ischemic mitral regurgitation may have a small left atrial cavity, depending on the acuity of presentation. Despite this, however, excellent exposure of the valve can be obtained with a standard mitral valve retractor system if certain principles are followed. The interatrial approach is most commonly used, and particular attention should be paid to the following: (1) complete dissection of the interatrial groove before atriotomy and (2) posterior extension of the inferior aspect of the atriotomy, with partial detachment of the right lower pulmonary vein. The trans-septal approach may be useful in the setting of a small left atrium or when an aortic prosthesis is present. A thoracotomy approach can be considered in reoperative setting and in primary cases that do not require concurrent CABG (if coronary arteries have been previously stented).

Valve Analysis

Before segmental valve analysis, it may be helpful to place an exposure suture in the posterior annulus at the junction between P1 and P2 to bring the valve apparatus anterior and lateral. Using two hooks, it is then possible to confirm the pathognomonic findings of secondary mitral regurgitation (i.e., posterior or bileaflet tethering, caused by papillary muscle displacement, with otherwise normal leaflets and no evidence of prolapse or fixed restriction; Fig. 92-17A). Associated annular dilation is also commonly present.

Suture Placement

For implanting an annuloplasty ring, 2-0 braided polyester sutures are most commonly used. Because of the

potential for increased tension in the setting of type IIIB dysfunction with associated annular dilation, it is preferable to place the sutures close together along the annulus. We prefer to use crossover sutures (see Fig. 92-17B) to help accommodate and distribute the excessive tension that a restrictive annuloplasty can impose on the annulus. Using the crossover technique, ring dehiscence is rare. The full curve of the needle should be used to encourage deep, wide placement of individual sutures along the annulus. The anterior commissure is usually the most difficult area to expose, and it is usually approached last, after the placement of sutures along the septal, medial, and lateral portions of the annulus to place tension on prior sutures to expose this area of the annulus.

Sizing and Implantation

After sutures are placed around the annulus, standard ring sizers are used to select the appropriate ring. Placing gentle traction on marginal cords in the A2 portion of the anterior leaflet with a hook allows the height and surface area of the anterior leaflet to be measured. An additional measurement to consider is the intercommissural distance.

Because leaflet restriction in ischemic mitral regurgitation results in less leaflet tissue available for coaptation, it is necessary to downsize the complete remodeling ring by one or two sizes to ensure an adequate surface of coaptation after annuloplasty. Systolic anterior motion is almost unknown, despite aggressive downsizing, because the restricted posterior leaflet cannot displace the anterior leaflet into the outflow tract. After a ring is selected (typically a size between 24 and 28 mm), the interrupted sutures are passed through it, with respect paid to the associated geometry of the annulus, crossing over on the prosthetic ring where sutures have been crossed on the annulus. The individual sutures are then tied, thus securing the ring to the annulus.

After the downsized remodeling annuloplasty is completed, a saline test is used to confirm the line of coaptation along the margin of the leaflets. The ink test confirms an adequate surface of coaptation.¹²² The typical appearance of a completed downsized remodeling annuloplasty is shown in Figure 92-16. Nearly the entire orifice is occupied by the anterior leaflet, thereby allowing the entire restricted posterior leaflet to contribute to coaptation.

Adjunctive Procedures

Although the routine use of a remodeling annuloplasty and more aggressive downsizing is likely to minimize the incidence of residual mitral regurgitation after CABG and annuloplasty to well less than 10%, there may be a small group of patients for whom annuloplasty alone is insufficient to correct the mitral regurgitation. A number of adjunctive techniques, applied with the restrictive annuloplasty, can help to eliminate or reduce residual regurgitation in such patients. Some physicians advocate routine use of adjunctive techniques in an expectation that they will yield a more durable repair; however, systematic application of adjunctive techniques has yet to be

FIGURE 92-17 ■ Surgical approach to ischemic mitral regurgitation in a patient with severe annular dilation symmetric leaflet tethering. **A**, After annular sizing primarily based on the surface area and height of the anterior leaflet, annular sutures are placed. Sutures at the position of the anterior commissure and trigon are placed last, taking advantage of previously placed sutures to expose the area. **B**, Interlocking sutures can be placed along P3 to reinforce the annuloplasty. **C**, Adjunctive techniques in addition to downsized rigid ring annuloplasty include cutting secondary chords to the anterior leaflet. **D**, Closure of leaflet clefts or indentations should be part of the surgical routine when attempting repair to avoid residual leaks because of the lack of tissue. **E**, A full remodeling Carpentier-McCarthy-Adams INR Etlogix ring is placed (disease-specific ring). **F**, Cutting secondary chords of the posterior leaflet can be an option after full repair in patients with generous posterior leaflet tissue.

shown to improve any of the key long-term outcomes (i.e., survival, heart failure, freedom from recurrent regurgitation).

Papillary Muscle Repositioning

Displacement of the papillary muscles is a key component in the pathophysiology of ischemic mitral regurgitation and, in theory, if the distance of displacement is reduced, then mitral regurgitation should be reduced or eliminated because of less leaflet tethering. Reduction in papillary muscle displacement can be achieved by various methods. Kron and coworkers¹²³ initially treated ischemic mitral regurgitation with papillary muscle repositioning using a pledgeted suture attached from the posterior papillary head to the annulus (Fig. 92-18). Rama and colleagues¹²⁴ described suturing the posterior to anterior muscle with autologous pericardial pledgets, whereas Hvass and associates¹²⁵ and Ito and coworkers¹²⁶ used a polytetrafluoroethylene tube to construct a sling around the base of the papillary muscles (see Fig. 92-18). Several variations of these procedures have been described, including some that allow physiologic adjustment of tethering distance on the beating heart.¹²⁷ Although several groups report promising midterm results, it has not been demonstrated that any papillary repositioning techniques result in clinical benefit compared with annuloplasty alone.

Secondary Chordae Cutting

Levine and Schwammenthal demonstrated in animal models that division of secondary mitral valve chordae reduces the degree of tethering in ischemic mitral regurgitation.¹²⁸ Borger and colleagues¹²⁹ reported on a series of 43 patients in whom a downsized annuloplasty was supplemented with dividing secondary chords to the restricted segments of the anterior leaflet, posterior leaflet, and commissures (see Fig. 92-17C and F). They compared these patients to 49 historical and concurrent controls who underwent annuloplasty alone. The authors observed less leaflet tenting and a lower incidence of early recurrent regurgitation in the chordal-cutting group. Application of the chordal-cutting technique was, however, limited to a few surgeons; therefore, differences in surgical skill or expertise may have contributed to the superior outcomes in the chordal-cutting subgroup. The annuloplasty-only group had a higher than expected incidence of early recurrent regurgitation—37% versus 15% in the chordal-cutting group—suggesting technical factors related to inadequate technique could have contributed to worse results in the controls. Chordal cutting can be performed through an aortotomy¹³⁰ and can achieve better reduction in anterior leaflet tenting. Some questions have been raised as to potential deleterious effects of chordal cutting on left ventricular function, but these have yet to be determined.

FIGURE 92-18 ■ Approaches to papillary muscle repositioning. **A**, Apical displacement of the posterior papillary muscle (PPM) causing tethering of both leaflets at the medial commissure, producing mitral regurgitation (MR; *left*). Placement of a traction suture relocates the tip of the PPM closer to the annulus, permitting better leaflet coaptation (*right*). **B**, A sling placed around the base of both papillary muscles and tightened reduces displacement of both muscles and thereby also reduces leaflet tethering. (Modified with permission from Kron IL, Green GR, Cope JT: Surgical relocation of the posterior papillary muscle in chronic ischemic mitral regurgitation. *Ann Thorac Surg* 74:600–601, 2002; and from Hvass U, Tapia M, Baron F, et al: Papillary muscle sling: a new functional approach to mitral repair in patients with ischemic left ventricular dysfunction and functional mitral regurgitation. *Ann Thorac Surg* 75:809–811, 2003.)

Other Approaches

Poor coaptation of the scallops of the posterior leaflet can occur with leaflet restriction; deep indentations or clefts (P1/P2 or P2/P3; see Fig. 92-17D) should be closed, particularly if a corresponding jet is noted on saline testing. Posterior leaflet patch extension (Fig. 92-19), especially over the P3 scallop, has been used in patients with severe posterior leaflet restriction.¹³¹ Although the edge-to-edge technique is used as an adjunct by some groups,^{36,132} laboratory and clinical data do not provide strong support for its use in surgical repair. Experimental animal work shows that the edge-to-edge repair does not

alter the annular, subvalvular, or leaflet geometric alterations seen in the disease. In vitro laboratory studies suggest that although the edge-to-edge repair can partially reduce regurgitation caused by annular dilation, it is not effective in correcting type IIIB dysfunction associated with papillary muscle displacement.¹³³ Edge-to-edge repair as an adjunct to annuloplasty can exaggerate the risk of mitral stenosis when performed in the context of a downsized annuloplasty. Finally, some surgeons have attempted ventricular solutions to ischemic mitral regurgitation, including plication of left ventricular infarct scar or external device application.¹³⁴

Is Restrictive Annuloplasty Harmful?

Restrictive annuloplasty, the mainstay of current therapy for ischemic mitral regurgitation, invariably results in a valve orifice that is smaller than would be expected for that particular valve, and it also fixes the annulus in a nonphysiologic shape and position. The size 24- to 28-mm rings that are typically used in this disease would be considered small for other pathologies. In theory, therefore, there is a risk of over-narrowing the orifice, resulting in functional mitral stenosis. One clinical study supports this theory. Magne and coworkers¹³⁵ compared 24 patients who underwent successful restrictive annuloplasty with 20 controls who had ischemic heart disease but no mitral regurgitation. They used dobutamine stress echocardiography to evaluate transvalvular gradients and functional capacity.¹³⁵ Compared with controls, patients who had restrictive annuloplasty had higher gradients at rest (13 vs. 4 mm Hg) and stress (19 vs. 6 mm Hg). They noted that the systolic pulmonary artery pressures rose to 58 mm Hg with stress in patients with restrictive annuloplasty (compared with 38 mm Hg in controls). The indexed orifice valve area at peak stress was 1.0 cm²/m² for the restrictive annuloplasty group (compared with 2.4 cm²/m² in control).¹³⁵ These data suggest that restrictive annuloplasty could induce some degree of functional mitral stenosis. The authors, though, did not correlate their findings with symptoms or survival, so it is not clear whether the observed hemodynamics have a bearing on clinical outcome. This study, however, has several limitations that limit the reliability of its findings,¹³⁶ and indeed other studies that have included systematic echocardiography did not observe functional stenosis.⁹⁸ Animal studies highlight other potentially deleterious effects of restrictive annuloplasty, such as inhibition of basal wall thickening¹³⁷ and abolishing of normal annular and leaflet dynamic motion,¹⁰³ but the effects of these changes have not been studied in a clinical setting.

Percutaneous Approaches

Because of the relatively high operative risk and uncertain benefit of mitral valve repair in patients with advanced cardiomyopathy and severe ischemic mitral regurgitation, there has been a surging interest in development of percutaneous approaches to treating ischemic mitral valve regurgitation. Attempts at percutaneous therapy for ischemic mitral regurgitation have largely been directed at either annuloplasty or edge-to-edge approaches.

FIGURE 92-19 ■ Posterior leaflet extension with a glutaraldehyde-fixed pericardial patch in patients with ischemic mitral regurgitation. The patch is sutured to the edge of the posterior leaflet defect and the posterior mitral annulus with a running 5-0 polytetrafluoroethylene suture.

Annuloplasty has been fraught with various technical problems, and it is not adequately developed for reproducible and effective application. In a multicenter study of 43 patients with secondary mitral regurgitation, while it was technically feasible to deploy an annuloplasty device in 30 patients, no significant changes were noted in severity of mitral regurgitation, ventricular volumes, or quality of life.¹³⁸ The most used percutaneous device in functional ischemic regurgitation is the MitraClip (Abbott Vascular, Santa Clara, CA), which is a cloth-covered cobalt-chromium device that permanently clips the anterior and posterior leaflets, thereby performing a percutaneous edge-to-edge repair. Studies have demonstrated that the MitraClip can reduce severity of secondary mitral regurgitation in patients with end-stage heart failure with most patients reported to have improved symptoms, reduction in left ventricular size and moderate or less regurgitation at short-term follow-up.^{139,140} The MitraClip, however, does not eliminate regurgitation in many patients (this is expected as has been demonstrated in surgical studies of edge-to-edge), and up to half the patients remain with residual mild or moderate regurgitation. It is not known whether residual regurgitation will have similar long-term negative prognostic effect in patients undergoing percutaneous therapy, as is the case with residual regurgitation after surgical repair. However, considering the severe symptomatic nature of these patients, the rationale for accepting the less perfect edge-to-edge results is that any reduction in mitral valve regurgitation may be worthwhile and potentially beneficial (the same would not hold for surgical repair because the high risk would not justify an incomplete repair). The MitraClip should, however, be reserved for patients who cannot have surgical repair, as the results of ischemic mitral regurgitation repair are superior with surgery than with the MitraClip in terms of long-term freedom from regurgitation and the early survival is similar with both approaches.¹³⁹ Of note, it has not been objectively demonstrated that the reduction in mitral regurgitation grade seen with the MitraClip affects either survival or quality of life compared with optimal guideline-directed medical therapy in patients with advanced heart failure; this is currently the subject of a multicenter randomized trial, Clinical Outcomes

Assessment of the MitraClip Percutaneous Therapy for Extremely High-Surgical-Risk Patients (COAPT), which should report in 2016 to 2018. It is possible that some of the presumed benefit of clip therapy arises from factors such as closer medical supervision and management, patient selection, and placebo effect. Of note, a recent systematic review of 16 studies reporting data on 2980 patients showed that despite a low procedural mortality (4.5% at 30 days), high-risk patients who had successful MitraClip repair still had high early mortality (16.4% at 310 days).¹⁴¹ A single center report of 109 patients with functional regurgitation reported a 3-year survival of 74.5%.¹⁴² It therefore is not clear whether the percutaneous edge-to-edge approach alters the natural history of these patients, as midterm results do not seem to be substantially different from historical controls. Until additional data emerge, therefore, the MitraClip is not considered for primary treatment of severe ischemic mitral regurgitation, except for symptomatic relief in select patients with severe advanced heart failure symptoms who have failed medical therapy and who are not candidates for mitral valve surgery because of excessive risk or presumed futility.

TYPE II ISCHEMIC MITRAL REGURGITATION

Patients with type II (mitral valve prolapse) ischemic mitral valve regurgitation are infrequently encountered in modern clinical practice. Type II ischemic regurgitation can be separated further into acute ischemic mitral valve regurgitation because of papillary muscle rupture or chronic ischemic mitral valve regurgitation secondary to papillary muscle elongation or rupture.

Acute Papillary Muscle Rupture

Historically, acute papillary muscle rupture was observed in up to 5% of patients with transmural myocardial infarction. However, the incidence of acute papillary muscle rupture, and other mechanical complications of acute myocardial infarction, has reduced remarkably in the era of early reperfusion postmyocardial infarction.¹⁴³

The posterior-medial papillary muscle is more susceptible to ischemia because of its dependence on a single vascular supply via a distal branch of either the right coronary or circumflex artery in contrast to the dual blood supply to the anterior muscle from the left anterior descending and diagonal systems. In the setting of acute coronary occlusion, a transmural papillary muscle infarction could potentially lead to muscle necrosis with subsequent rupture of the trunk or one or more of the papillary heads. Usually, the timing of rupture is about 1 week after the initial infarct. Because of the evolution of medical and interventional reperfusion strategies, acute papillary muscle rupture is rare. It must still be considered in the setting of a new systolic murmur and hemodynamic collapse, typically cardiogenic shock, occurring in the first several days after myocardial infarction. Echocardiography is the mainstay for distinguishing the condition from acute ventricular septal defect, free-wall ventricular rupture, or global myocardial dysfunction, which can all produce a similar picture in the setting of transmural myocardial infarction. Lack of a step up in venous oxygen saturation also distinguishes this condition from an acute ventricular septal defect. Once the diagnosis is made, hemodynamic stabilization is usually facilitated by placement of an intra-aortic balloon pump. Surgery should not be delayed, except to optimize hemodynamics and invasive monitoring, because the mainstay of therapy is to correct the embarrassment of massive acute mitral valve regurgitation.

Mitral valve repair with reimplantation of the papillary muscle either into an adjacent nonischemic head or the ventricle can be done, but it is rarely undertaken. One must ensure that the infarcted head itself can hold sutures, usually placed at the insertion of the chordae, and that the reimplantation occurs into an area of viable tissue. Replacement of the chordal apparatus with polytetrafluoroethylene is also feasible, albeit with little known about long-term results in this setting. By far the most common treatment for acute papillary muscle rupture due to myocardial infarction is an expeditious mitral valve replacement. Coronary revascularization is undertaken at the same setting. Surgery carries a high hospital mortality of around 20% in most series.¹⁴⁴⁻¹⁴⁶ Because the burden of coronary disease is low, patients with this condition who survive the initial insult actually have better long-term survival compared with patients with type IIIB ischemic mitral valve regurgitation with long-standing ventricular remodeling and who undergo mitral valve surgery.

The Mayo group¹⁴⁵ analyzed long-term outcomes of 54 patients who had surgery (valve replacement, 41; valve repair, 13) for papillary muscle rupture between 1980 and 2000. As expected, 90% involved the posterior papillary muscle. The overall operative mortality was 18.5%, with most deaths occurring because of low cardiac output or ventricular rupture. Although mitral valve repair was associated with a lower mortality (7.7% vs. 22% for replacement; $P = 0.21$), most repairs were done in the recent era, in which improved outcomes were observed (operative mortality post-1990 was 10%). Patients who had concurrent CABG also had a lower operative mortality. Once patients survived hospitalization, midterm survival was reasonable, with 52% alive and free from heart

FIGURE 92-20 ■ Overall (including operative mortality) long-term survival (green line) and long-term survival free of congestive heart failure (CHF; red line) after surgery for postinfarct papillary muscle rupture. Numbers indicate the 5- and 10-year survival ($\pm$ standard error). failure at 5 years (Fig. 92-20). Six patients developed moderate or greater mitral regurgitation in the follow-up period—four after valve repair, and two after valve replacement.

Chronic Type II Ischemic Mitral Regurgitation

Perhaps even rarer than acute papillary muscle rupture in ischemic mitral valve regurgitation is the occurrence of leaflet prolapse because of elongation, thinning, and fibrosis or rupture of a chronically infarcted papillary muscle. It is usually misdiagnosed preoperatively as degenerative valve disease with chordal elongation with concomitant coronary artery disease. Valve analysis in the operating room generally reveals a fibrotic and thinned-out papillary muscle with normal chords and prolapse of the affected segment owing to elongation of the muscle. The nonprolapsing segments often show a type IIIB restriction. In terms of treatment, chronic type II ischemic regurgitation can usually be treated with valve repair. This lesion condition can be treated like chordal rupture or elongation, as seen in degenerative disease, and it is amenable to a variety of repair techniques. PTFE chordal replacement, chordal transfer, and limited resection and papillary transposition are among repair techniques that can be used to treat this condition. A downsized annuloplasty can also be performed in view of the ischemic etiology and associated type IIIB dysfunction.

Jouan and colleagues¹⁴⁷ reported a series of 44 patients who had surgery for ischemic mitral valve prolapse, of which 66% had chronic mitral regurgitation (more than 60 days after myocardial infarction), whereas the others were operated within 60 days of myocardial infarction. This series included four emergent surgeries. Interestingly, isolated chordal rupture owing to chordal infarction was the postulated mechanism of regurgitation in six patients. The remainders were due to papillary muscle elongation (36%) or rupture (50%). Most of the papillary

FIGURE 92-21 ■ Classification of papillary muscle rupture according to Jouan and colleagues.¹⁴⁷ **A–C**, Partial rupture, typically present in subacute or chronic fashion. **D**, Classic papillary muscle rupture. Mechanisms of ischemic mitral valve prolapse are shown. **A**, Necrosis of a separate commissural head (inserted close to the annulus) with rupture of the anchorage of the commissural chord. **B**, Necrosis of a single head papillary muscle subdivided in multiple heads with partial rupture. **C**, Necrosis of a fenestrated papillary muscle with detachment of its main insertion: “incomplete” rupture. With time, incomplete rupture mimics papillary muscle elongation. **D**, Single papillary muscle with complete and total rupture.

muscle ruptures were partial or incomplete, thus explaining the subacute or chronic presentation (Fig. 92-21), in contrast to the more dramatic presentation of total rupture (see Fig. 92-21). In addition, all patients had a component of type I or IIIB dysfunction. Mitral valve repair was performed in all but 2 patients. The 5-year survival was 68%, which is comparable to that in type IIIB dysfunction. Repair in the context of ischemic prolapse is expectedly less durable than for prolapse because of degenerative disease, as evident in the 10% actuarial reoperation rate and 30% recurrent moderate or greater mitral regurgitation rate at 5 years, because of greater propensity to recurrence of regurgitation from ongoing ventricular remodeling and from failure of papillary muscle suture techniques when used.

SUMMARY

Disruption of the ventricular septum after myocardial infarction is an infrequent event after a full-thickness myocardial infarction. The resulting clinical syndrome can range from an asymptomatic murmur to an extensive left-to-right intracardiac shunt with resulting heart failure and shock. The first approaches to surgical management emphasized delayed repair, which allowed time for fibrosis to occur so that tissue quality at the defect margins was more substantial.^{1,2} Modern approaches recognize that potentially salvageable patients deteriorate during this period of delay. Thus, early surgical intervention is now the accepted treatment.³

HISTORICAL PERSPECTIVE

Postinfarction ventricular septal defect (VSD) was first recognized by Latham at autopsy in 1845.⁴ The first antemortem diagnosis was made in 1923.⁵ In 1956,

Cooley accomplished the first successful surgical repair in a patient who had survived several weeks after septal perforation.⁶ Most patients in the early era were brought to operation a month or longer after surviving acute infarction with the belief that organization of the tissues surrounding the defect would allow a more secure closure.^{1,2} Subsequently, improvements in myocardial protection, the design and refinement of surgical techniques, improved prosthetic materials, and the widespread use of cardiac ultrasonography to permit the earlier diagnosis of VSD have all contributed to making earlier successful repair of this entity a possibility.⁷

INCIDENCE AND DEMOGRAPHICS

Postinfarction VSD complicates 1% to 2% of myocardial infarctions, but it accounts for 5% of deaths after myocardial infarction.^{8,9} The incidence appears to be

declining because of aggressive pharmacologic and interventional management of acute myocardial infarction and better treatment of postinfarction hypertension.¹⁰⁻¹² Postinfarction VSDs occur more frequently in males (male-to-female ratio, 3:2), reflecting the higher incidence of coronary artery disease in men. The average age is 62 years (range, 44 to 81 years). Septal rupture occurs most often after the first acute myocardial infarction.¹³

ETIOLOGY AND PATHOGENESIS

Angiographic evaluation of patients with postinfarction VSD most often reveals a completely occluded culprit coronary artery.⁶ Nearly two thirds of patients have single-vessel disease.¹⁴ There is usually somewhat less extensive disease in other vessels, and less collateralization.¹⁵ Postinfarction VSDs are located most commonly (i.e., in ≈60% of cases) in the anteroapical septum as a result of full-thickness anterior infarction secondary to occlusion of the left anterior descending artery. Twenty percent to 40% of patients with postinfarction VSD have rupture of the posterior septum because of inferoseptal infarction secondary to occlusion of a dominant right or a dominant circumflex coronary artery (Fig. 93-1).¹⁶ Simple rupture, consisting of a direct through-and-through defect, tends to be more common and is usually located anteriorly. Complex rupture with a more serpiginous tract is less common and is usually located inferiorly. Although a single VSD develops in most patients, 5% to 11% of patients may have multiple septal defects.

The myocardial infarction that sets the backdrop for a postinfarction VSD tends to be extensive and has been reported to involve 26% of the free wall on average, compared with only 15% in noncomplicated acute myocardial infarctions.⁸ Postinfarction VSD usually develops

two to four days after acute myocardial infarction, but it has been reported as early as a few hours after acute myocardial infarction and up to two weeks later.^{8,17,18} This time course correlates with histologic findings that show extensive distribution of necrotic myocardium at this time, with relatively sparse vasculogenesis, angiogenesis, or formation of fibrous connective tissue.^{19,20} It has been hypothesized that “slippage” of myocytes during infarct expansion may allow blood to dissect through the necrotic myocardium, where it can enter the right ventricle (or the pericardial space in the setting of rupture of the free wall).^{21,22} Similarly, autodigestion of necrotic myocardium may allow fissures to form, through which blood can subsequently dissect.²³

Left-ventricular free-wall rupture can occur in 4% to 8% of myocardial infarctions^{24,25} and is responsible for 15% of deaths after acute myocardial infarction.²⁶ Free-wall rupture typically occurs one to four days after infarction and is easily diagnosed with echocardiogram.²⁴ Acute rupture is almost always fatal; however, some patients with subacute rupture can be saved, but they require emergent surgical intervention.^{24,26}

PATHOPHYSIOLOGY

The primary determinant of outcome after postinfarction rupture of the ventricular septum is the development of heart failure (left, right, or biventricular), which is a function of both the size of the defect and the magnitude of the myocardial infarction. Left-sided heart failure tends to predominate in anterior VSDs, and right-sided failure predominates in posterior VSDs.²⁷⁻²⁹ The extent of heart failure often cannot be explained solely by postinfarction failure of the ventricle.³⁰ With the opening of a defect in the ventricular septum, a proportion of each left ventricular ejection is diverted from the systemic circulation across the septum into the right ventricle, thereby both compromising forward systemic cardiac output and overloading the pulmonary circulation. The resulting cardiogenic shock can lead to end-organ malperfusion and organ failure, which may be irreversible and fatal. In addition, the normally compliant right ventricle may demonstrate severe diastolic failure after a prolonged left-to-right shunt. The resulting escalation in right ventricular (RV) diastolic pressures can ultimately result in flow reversal across the septum when RV end-diastolic pressures exceed left ventricular end-diastolic pressures³¹ and compound the situation further with systemic hypoxia.

NATURAL HISTORY

Without surgical intervention, one-quarter of patients with postinfarction VSD die within 24 hours. Half will succumb to their illness within the first week, nearly two-thirds will die within two weeks, three-quarters will die within a month, and only 7% will survive longer than one year.^{13,32,33} These data have been confirmed in the recent SHOCK (SHould we emergently revascularize Occluded Coronaries in cardiogenic shock) multicenter trial, in

FIGURE 93-1 ■ Distribution of postinfarction ventricular septal defects. LAD, Left anterior descending.

which subgroup analysis of patients who had postinfarction VSD was performed. A total of 55 patients with postinfarction VSD were enrolled in the study a median of 16 hours after infarction and went into shock 7.3 hours thereafter. Of the 24 patients treated medically, only one survived (survival rate, 4%). Of the 31 patients who underwent operation to repair the VSD, 21 underwent concomitant coronary artery bypass grafting. Of these, only six survived (survival rate, 19%). The difference between the groups was statistically significant.³⁴

The historical practice of waiting weeks after postinfarction rupture of the ventricular septum selected out patients with lesser pathology and a relatively mild hemodynamic insult.^{28,35,36} It is clear that attempting to defer early operation in the hopes of maintaining hemodynamic stability deprives many patients of a chance for a successful outcome before irreversible end-organ damage supervenes.^{37,38}

CLINICAL PRESENTATION, PREOPERATIVE MANAGEMENT, AND RISK STRATIFICATION

Presentation

Typically, patients with postinfarction VSD present several days after a myocardial infarction with a harsh new holosystolic murmur that may radiate to the axilla.¹⁸ In more than half of patients, this is associated with recurrent chest pain.⁸ Clinical signs are generally those of right-sided heart failure, and pulmonary edema is rare. The electrocardiographic findings in these patients are the changes seen in antecedent anterior, septal, inferior, or posterior infarction. As much as one third of patients may develop transient atrioventricular conduction block that precedes rupture. Chest roentgenogram is generally nonspecific. Unfortunately, there is no reliable predictor of impending rupture.

This clinical syndrome may resemble acute mitral regurgitation secondary to rupture of a papillary muscle. In fact, both entities may coexist and sometimes can be distinguished only by imaging techniques. On physical examination, the murmur associated with postinfarction VSD is more prominent at the left lateral sternal border, is loud, and is associated with a thrill in more than half of patients. In addition, septal rupture is more commonly associated with anterior infarcts and conduction anomalies, whereas papillary muscle rupture is usually associated with posterior infarction and no conduction anomalies. If the patient is deemed salvageable, immediate placement of intra-aortic balloon pump and early operation are the management strategy of choice.

Diagnosis

The classic technique for distinguishing between acute papillary muscle rupture and postinfarction VSD has been right heart catheterization, during which a greater than 9% step-up in the oxygen saturation between the right atrium and the pulmonary artery is diagnostic of VSD in the appropriate clinical setting.²⁸ Additional

findings, such as an elevated pulmonary-to-systemic flow ratio, which can range from 1.4:1 to 8:1, also verify the presence of the VSD and roughly correlate with size.³⁹ Neither of these techniques accurately localizes the defect. Color-flow Doppler echocardiography can show the size and location of the defect, determine ventricular function, assess pulmonary artery and RV pressures, and exclude concomitant mitral valve disease with sensitivity and specificity approaching 100%.⁴⁰⁻⁴³

Indications for Operation and Preoperative Management

Because the natural history of untreated postinfarction VSD is dismal, the diagnosis of this entity suffices as an indication for operation.³⁸ Patients in cardiogenic shock represent a surgical emergency. Sometimes patients are already in established multisystem organ failure. These patients are unlikely to survive emergent repair and may benefit from a mechanical bridge (e.g., intra-aortic balloon counterpulsation or ventricular assist device) for salvage before corrective surgery. Patients in an intermediate status between shock and stable condition need to have surgical repair within 12 to 24 hours after appropriate preoperative evaluations are completed. A small percentage of patients (<5%) who are completely stable with no clinical compromise can undergo repair on a semi-elective basis.

Preoperative management is directed toward maintaining hemodynamic stability and preventing end-organ damage. Specifically, therapy should be targeted toward reducing systemic vascular resistance (thereby reducing left-to-right shunting), maintaining cardiac output and peripheral perfusion, and maintaining or improving coronary blood flow. All three of these objectives can be accomplished by intra-aortic balloon counterpulsation⁴⁴⁻⁴⁶ or with directed pharmacologic therapy.

Predictors of Risk

Patients with postinfarction VSD comprise a heterogeneous group in which both extremes of risk (i.e., very low risk and very high risk) are possible. For the nonemergent, stable patients, excellent results can be achieved, probability of survival to discharge from the hospital is high, and long-term survival is comparable with that in common cardiac operations. Conversely, patients in extremis tend to have dismal outcomes (Table 93-1).

In various studies, clinical variables have been used to identify the high-risk patient. In several studies, the use of an intra-aortic balloon pump was correlated with increased early mortality⁴⁷; presumably, its use was seen as a marker for disease severity. Other groups have demonstrated that posterior location of the septal rupture is associated with an increased operative mortality,^{28,31,48,49} which may be because the repair is more technically difficult, because the risk of mitral regurgitation is increased, or because RV failure is associated with an RV infarction. Proximal VSDs (closer to the atrioventricular groove) have also been shown to strongly predict early mortality, presumably because they are associated with the largest infarctions.⁵⁰

TABLE 93-1 Preoperative Predictors of Death after Surgical Repair of Postinfarction VSD

Variable	Predictor of Early Death	Predictor of Late Death
Need for preoperative catecholamines	$P = 0.001$	$P = \text{NS}$
Emergent operation	$P < 0.0001$	$P = \text{NS}$
Anterior VSD	$P = 0.04$	$P = \text{NS}$
Age > 65 years	$P = 0.009$	$P = \text{NS}$
Right-sided heart failure	$P = 0.01$	$P = 0.005$
Elevation in blood urea nitrogen	$P = 0.02$	$P = \text{NS}$
Elevation of serum creatinine	$P = \text{NS}$	$P < 0.05$
Previous myocardial infarction	$P = \text{NS}$	$P < 0.05$
Presence of left main coronary disease	$P = \text{NS}$	$P < 0.05$

VSD, Ventral septal defect.

OPERATIVE MANAGEMENT

General Principles

Cardiopulmonary bypass is established with bicaval venous drainage and cannulation of the ascending aorta. The patient is cooled, and cardiac standstill is achieved with blood cardioplegia via the antegrade and retrograde routes. A variety of alternative strategies for myocardial protection are practiced at Massachusetts General Hospital, including continuous warm-blood cardioplegia, fibrillatory arrest, and cold-blood cardioplegia.⁵¹⁻⁵⁴ If myocardial revascularization is to be performed, it should be done before opening the ventricle, to optimize myocardial protection. The general principles of this operation include meticulous attention to myocardial protection, a transinfarct approach to the VSD, thorough trimming of the left ventricular margins of the defect, conservative trimming of the right ventricular margin, close inspection of the papillary muscles and mitral apparatus, a tension-free repair, placement of the patch on the endocardial surface, and buttressing of the repair with Teflon felt to prevent sutures from cutting through the friable muscle.

Infarctectomy

Apical Amputation

The technique of apical amputation was first described by Daggett.³ An incision is made through the infarcted apex of the left ventricle. Débridement of the necrotic myocardium back to healthy muscle results in amputation of the apex of the heart, including the left ventricle, right ventricle, and septum. The remaining apical portions are then reapproximated to the apical septum using a row of interrupted mattress sutures of 0 Tefdek passed sequentially through a buttressing strip of Teflon felt, the left ventricular wall, a second strip of felt, the septum, a third strip of felt, the right ventricular wall, and a fourth strip

of felt. After all of these sutures have been tied, the closure is reinforced with an additional running suture.

Free-Wall Rupture

There have been numerous surgical techniques described for repair of free-wall rupture. Many have advocated closing the defect with infarctectomy and prosthetic patch repair while the patient is on cardiopulmonary bypass.⁵⁵⁻⁵⁸ The use of cardiopulmonary bypass is fraught with difficulty because of the systemic heparinization causing continuous oozing of blood through necrotic myocardium.⁵⁵ For this reason, many clinicians have advocated repair without extracorporeal bypass using an epicardial patch.⁵⁹⁻⁶¹ More recently, the use of a prosthetic patch with surgical glue has been advocated for patients without blowout rupture. The advantage of this technique is that it allows for a simple and expedited repair.⁶²

Anterior Septal Rupture

These defects are approached via a left ventriculotomy through the infarct. If the defect is small, it can be closed by plication with primary closure.⁶³ Most defects are larger and require closure with a Dacron prosthetic patch after débridement of necrotic myocardium. This operation is performed by placing a series of pledgeted interrupted mattress sutures around the perimeter of the defect. Sutures are passed through the septum from right to left along the posterior rim, and they are passed from the epicardium to the endocardium along the anterior rim. Once all the sutures are laid, the patch is inserted and all sutures are pledgeted again and then tied. The edges of the ventriculotomy are then reapproximated in a double-layer closure that is buttressed with Teflon felt or glutaraldehyde-preserved bovine pericardium (Fig. 93-2).

Posteroinferior Septal Rupture

Posterior VSD poses the greatest technical challenge (Fig. 93-3). Simple plication has an extremely high failure rate, and the procedure is often complicated by a reopening of the defect or by catastrophic disruption of the infarctectomy closure. Use of the following technique has been associated with improved operative results. After the establishment of cardiopulmonary bypass, the left heart is vented via the right superior pulmonary vein. The heart is then delivered from the pericardial well as for bypass to the posterior descending coronary artery. The infarct may include both ventricles or may be limited to the left ventricle only. The left ventricle is opened in standard fashion and infarctectomy is performed. The mitral apparatus is inspected, and mitral valve replacement is performed only in the setting of frank papillary muscle infarct. This is performed through a separate left atriotomy. The left ventricle needs to be aggressively débrided, but right ventricular débridement can be limited to only as much tissue as is needed to visualize the VSD. If the posterior septum has simply separated from the free wall, it can be reapproximated primarily in

FIGURE 93-2 ■ Technique of repair of anterior postinfarction ventricular septal defect by infarctectomy and patch repair.

FIGURE 93-3 ■ Technique of repair of posterior postinfarction ventricular septal defect by infarctectomy and patch repair.

a double-layered buttressed closure. Larger defects require patch closure as described earlier. The only difference is that sutures are placed from the right side of the septum and from the epicardial side of the right ventricular free wall. The most important aspect of this operation is to perform a separate patch closure of the

infarctectomy, because primary closure of this large tissue defect with its friable edges under tension has historically resulted in catastrophic disruption. We use a Hemashield Dacron graft (Boston Scientific, Natick, MA) for this purpose and pass sutures through the patch, which is seated on the epicardial surface of the heart, and then

through the margin of the infarctectomy, from the endocardium to the epicardium. Using an appropriately sized patch can result in restoration of normal ventricular geometry.

Infarct Exclusion with Endocardial Patch Repair

The technique of infarct exclusion with endocardial patch repair emphasizes the importance of restoring normal ventricular geometry as an attempt to preserve or restore ventricular function.^{52,53,63-65} The operative strategy is an extrapolation of the technique of Dor and colleagues, ventricular endoaneurysmorrhaphy⁶⁶—which involves intracavitary placement of an endocardial patch to exclude both the septal defect and the infarcted myocardium from the high-pressure zone of the ventricle—while maintaining ventricular geometry, which theoretically enhances ventricular function. Other theoretical benefits of this approach include avoiding resection of the myocardium (which could further compromise ventricular function), and avoiding a suture line in friable muscle (to diminish postoperative bleeding and disruption of the repair).

David and coworkers²⁷ pioneered this technique, which involves exposing the interventricular septum via a left ventriculotomy through the infarcted anterior wall 1 to 2 cm from the left anterior descending coronary artery. Stay sutures are placed in the ventricular wall to aid in exposure of the septal defect. These authors used a glutaraldehyde-fixed bovine pericardial patch for the repair. The patch is tailored to the endocardial shape of the ventricular infarction (generally about 4 × 6 cm) and is then sutured to healthy muscle (on the endocardial surface) surrounding the septal defect with a continuous 3-0 polypropylene suture. The repair is then carried onto the noninfarcted endocardium of the anterolateral ventricular wall with stitches that are approximately 5 to 7 mm deep and 4 to 5 mm apart. The ventriculotomy is then closed over the patch in two layers and is buttressed with two strips of glutaraldehyde-fixed bovine pericardium. In the case of a posterior septal defect, exposure is achieved via a posterior ventriculotomy with the heart elevated as for bypass grafting to the posterior descending artery.

The repair commences with anchoring of the patch to the fibrous annulus of the mitral valve with a 3-0 continuous polypropylene suture starting at a point corresponding to the posteromedial papillary muscle and moving medially toward the septum until the noninfarcted endocardium is reached. The stitch is then transitioned onto the septal endocardium using the technique described earlier. In this area of the repair, the suture should be reinforced with interrupted, pledgeted sutures. The lateral edge of the patch is sutured to the posterior left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. These need to be full-thickness stitches, and they should be buttressed with epicardial bovine pericardium or Teflon felt. Again, the ventriculotomy is closed in two layers of full-thickness sutures buttressed with bovine pericardium or Teflon felt.

Intraoperative Management

Coronary Artery Disease

For patients with postinfarction VSD, the value of preoperative coronary artery angiography and coronary revascularization is controversial. Many of these patients have multivessel coronary disease, and bypassing significantly diseased vessels may increase both early and long-term survival.^{27,28,35,64,67,68} Our approach is to perform catheterization when the clinical scenario permits, and to perform concomitant revascularization when indicated. The arguments against simultaneous revascularization are that (1) it provides no additional benefit⁶⁹⁻⁷¹ and (2) it subjects patients to preoperative left-side-of-the-heart catheterization, a time-consuming and potentially dangerous procedure. However, one study has found that concomitant revascularization with VSD repair improves early and long-term survival.⁷² Other groups have proposed selective left heart catheterization and revascularization^{7,73}—avoiding it in patients when a postinfarction VSD is thought to be the result of their first infarction—provided there is no history of angina and no electrocardiographic evidence of previous or ongoing ischemia in another territory.

Weaning from Cardiopulmonary Bypass

We have found routine intraoperative use of a transesophageal echocardiogram to be invaluable for assessing ventricular function, dimensions, residual shunt, and mitral regurgitation when weaning from bypass. For left heart dysfunction, we favor the use of intra-aortic balloon counterpulsation and the use of one of the phosphodiesterase inhibitors, such as milrinone, in the postoperative setting. Strategies to ameliorate right heart failure aim to limit right ventricular afterload while maintaining systemic blood pressure. This can be achieved by right-sided administration of prostaglandin E₁ (0.5 to 2.0 mg/min) with left-sided administration (via a left atrial line) of norepinephrine.⁷⁴ Finally, inhaled nitric oxide (20 to 80 ppm) selectively dilates the pulmonary circuit and may be efficacious in ameliorating right heart failure.⁷⁵ An inability to wean a patient from cardiopulmonary bypass is unusual if the repair has been successful. If there exists the inability to wean from cardiopulmonary bypass, institution of mechanical assist (left ventricular assist device, right ventricular assist device, or extracorporeal membrane oxygenation) may be considered.

Bleeding

When repairing postinfarction VSD, we generally use antifibrinolytic therapy with either aprotinin or ε-aminocaproic acid before commencing cardiopulmonary bypass. Other maneuvers to avoid postpump suture-line bleeding include application of fibrin sealants to the proposed suture line before repair⁷⁶ and the use of biological glues after surgical repair.⁷⁷ As a last-resort measure, Baldwin and Cooley⁷⁸ have used placement of a left ventricular assist device solely as an adjunct to the

repair of friable or damaged myocardium to decrease left ventricular distention, thereby controlling bleeding.

Percutaneous Closure

Successful transcatheter closure of postinfarction ventricular septal rupture, or closure of residual defects after repair, has been reported with increasing frequency. Early experience was with the CardioSEAL device (Nitinol Medical Technologies, Boston, MA), a nitinol double-umbrella prosthesis, which is a transvenous clamshell device.⁷⁹ Use of other catheter devices has also been attempted, including the Amplatzer septal occluder and the Rashkind double umbrella.^{37,80}

The Amplatzer VSD device allows closure of muscular and membranous VSDs, and it can be used for larger postinfarction defects. In a series of seven patients treated with the Amplatzer, the size of the device ranged from 12 to 24 mm, and there was only one death.⁸¹ The use of such devices in an overall treatment strategy is unclear because data suggest that the devices have a high early failure rate. The most attractive role has been its use in the unstable surgical patient, but data on outcomes in this group are difficult to evaluate and not yet well characterized. Catheter approaches appear to be most effective for treating recurrent or residual defects, and we preferentially use them for these conditions.⁸²

Delayed Repair

Sometimes a patient presents with evidence of severe end-organ dysfunction. As was discussed earlier, the risk of repair may be prohibitive in these patients, and consideration should be given to delayed repair. Placement of a ventricular assist device for a defined period of time has the theoretical advantage of allowing reversal of end-organ dysfunction, allowing maturation of the infarct and leading to firmer tissue that could make the closure less prone to technical failure, and permitting recovery of the stunned and energy-depleted myocardium. In our limited experience, this strategy has promise and merits further evaluation. Biventricular support is necessary if instituting left ventricular support results in right-to-left shunting.⁸³

Role of Ventricular Assist Devices

In selected patients, there may be a role for temporary mechanical heart support. The successful use of ventricular assist devices with staged repair of ventricular septal rupture has been described.⁸⁴⁻⁸⁶ Mechanical support may aid in reversing end-organ dysfunction, providing time for maturation of the infarct and leading to firmer tissue. Caution is required, however, because of the potential for high right-to-left shunting across the ventricular septum, which was reported to cause hypoxic brain injury in a patient with postinfarction VSD who was placed on a Heart-Mate left ventricular support device.⁸³ It is preferable that biventricular support be considered when using mechanical assistance in these patients. In addition to shunting, embolization of necrotic debris is possible, with the potential to cause obstruction in support devices.⁸⁷

Postoperative Management

The postoperative care of these patients is similar to that of other patients undergoing extensive intracardiac operations. Early postoperative diuresis is important to decrease the arterial-alveolar gradient induced by the increased extravascular pulmonary fluid associated with cardiopulmonary bypass. A continuous furosemide drip may sometimes be needed. If the patient suffers from renal dysfunction, we favor early institution of continuous venovenous hemofiltration. Intractable postoperative ventricular arrhythmias are treated with intravenous amiodarone.⁸⁸

OUTCOMES

Operative Mortality

Operative mortality (death before discharge or within 30 days of operation) ranges from 30% to 50% (see Table 93-1). David and colleagues²⁷ reported outstanding results with the infarct exclusion technique, with only a 19% early mortality rate. Regardless of technique, the most common cause of death after repair of a postinfarction VSD is low cardiac output (52%). Technical failures such as recurrent or residual VSD are the second most common causes of death (22%). Other causes of death include sepsis (17%), recurrent infarction (9%), cerebrovascular complications (4%), and intractable ventricular arrhythmias.

Long-Term Results

Most series report 5-year actuarial survival between 40% and 60% (Table 93-2).^{28,89-96} In the Massachusetts General Hospital experience, hospital survivors demonstrated 1-, 5-, and 10-year survival rates of 91%, 70%, and 37%, respectively (Fig. 93-4); 75% reported New York Heart Association (NYHA) class I functional status and 12.5% reported class II functional status after surgery.¹⁰ These favorable results have also been reported by other groups. Gaudiani and coworkers reported an 88% 5-year survival

FIGURE 93-4 ■ Postdischarge survival rates after repair of postinfarction ventricular septal defect: The Massachusetts General Hospital experience.

TABLE 93-2 Recent Clinical Experience* with Surgical Repair of Postinfarction Ventricular Septal Defect

Massachusetts General Hospital ¹	Boston	2002	114	37	45
University Hospital ⁶³	Zurich	2000	54	26	52 [†]
Glenfield General Hospital ²⁷	Leicester	2000	117	37 (30-day)	46
The Toronto Hospital ²⁴	Toronto	1998	52	19	65 [†]
Southampton General ²⁰	Southampton	1998	179	27	49
MidAmerica Heart Institute ⁴⁶	Kansas City	1997	76	41	41
Green Lane Hospital ³¹	Auckland	1995	35	31 (30-day)	60 [†]
Hôpital Cardiologique du Haut-Lévêque ²⁸	Bordeaux	1991	62	38	44
CHU Henri Mondor ⁵³	Créteil	1991	66	45	44

*Series with fewer than 25 patients and no 5-year follow-up were excluded.

[†]Value estimated from published graphic or tabular data.

rate, with 74% of survivors in NYHA functional class I.⁶⁷ David and colleagues reported a 66% 6-year survival,²⁷ and Davies and associates reported a 5-year survival rate of 69%.⁷³

Recurrent Septal Defects

In 10% to 25% of patients, recurrent or residual VSD may develop,²³ which could result from the reopening of a closed defect, the presence of an overlooked defect, or the development of a new defect in the early postoperative period. Small defects that occur as a result of leaks around the patch are usually asymptomatic and can be controlled with diuretic therapy. Larger defects or those causing symptoms or heart failure should be closed. These attempts may be made first in the catheterization laboratory.

SUMMARY

Although the prevalence of postinfarction VSDs has decreased with modern management of acute myocardial infarction, patients who do come to surgical attention are older and sicker and have complex comorbidities. Surgery is complex and relatively infrequent, and although the results are far better than if the patient had received no treatment at all, morbidity and mortality rates remain high. The use of predictive statistical models can assist us further in helping determine which patients should come to operation early, which patients would be better off temporized with the use of an assist device, and which patients should be turned down or treated percutaneously.

Coronary Artery Vasculitis

Polyarteritis Nodosa

Systemic Lupus Erythematosus

Wegener Granulomatosis

Takayasu Disease

Mucocutaneous Lymph Node Syndrome (Kawasaki Disease)

Intimal Proliferation and Fibrosis

Ionizing Radiation

Cardiac Transplantation

Extrinsic Coronary Artery Compression

SUBSTANCE ABUSE

Greater than 95% of patients with myocardial ischemia will have underlying atherosclerotic coronary artery disease as the etiology, with the remaining 5% possessing a range of congenital and acquired lesions. Although these lesions are rare individually, clinicians will inevitably encounter some form of nonatherosclerotic coronary artery disease in their practice.

These disorders can be broadly classified as congenital or acquired. Congenital coronary anomalies occur secondary to atresia, an abnormal origin, or abnormal drainage. Acquired disorders can be secondary to mechanical injury to the coronary artery or result from progressive occlusive disease unrelated to atherosclerosis. Diagnosis may be difficult because these disorders may be asymptomatic or may occur in patient populations in which cardiovascular disease is unsuspected. Given the rarity of certain types of these disorders, management recommendations may be based on limited series or expert opinion.

CORONARY ARTERY ANOMALIES

Anomalous Aortic Origin of Coronary Arteries

Approximately one third of all coronary artery anomalies are an anomalous aortic origin. Although multiple variations have been reported, with each of the three major coronary arteries arising from any of the three sinuses of Valsalva, most are benign. The exceptions to this include the right coronary artery arising from the left aortic sinus, and the left main coronary artery arising from the right aortic sinus, both of which are associated with a risk of sudden death.^{1,2}

The incidence of sudden death associated with a left main coronary artery arising from the right sinus of Valsalva has been reported to be as high as 57% and is most commonly seen with exercise.³ When symptomatic,

patients will present with angina, myocardial infarction, congestive heart failure, or syncope. From its origin in the right sinus of Valsalva, the left main coronary artery may pass anterior to the pulmonary artery, posterior to the aorta, between the great vessels, or through the conal septum. This anatomic position is believed to result in ischemia because of acute angulation resulting in a narrowed coronary orifice, compression of the artery from the adjacent great vessels, and compression by the inter-coronary commissure.^{3,4}

The incidence of sudden death from the right coronary artery arising from the left sinus of Valsalva has been reported to be as high as 25% and, as with the left main coronary artery arising from the right sinus, is often exercise related.^{3,5} When symptomatic, patients will present with angina, myocardial infarction, conduction disturbances, or syncope. The risk of ischemia is felt to result from ostial obstruction or arterial compression by the aortic root during diastole.⁴

The most common variation in anomalous aortic origin of the coronaries is a circumflex arising from the right sinus of Valsalva, or from the right coronary artery (Fig. 94-1). This condition in general does not manifest with symptoms and is diagnosed incidentally. Because the risk of sudden death is minimal, intervention is not needed.

For all anomalous aortic origins of the coronaries, angiography is needed to delineate anatomy and for surgical planning. In the presence of symptoms, surgery is indicated for all patients. For an anomalous left main coronary artery originating from the right sinus of Valsalva, coronary unroofing is recommended regardless of the presence of symptoms and should be performed urgently if symptoms are present. For patients with an anomalous right coronary artery from the left sinus of Valsalva (Fig. 94-2), surgery should be performed for symptoms, but there remains debate about surgery for the asymptomatic patient.⁴ Surgical options include unroofing of the coronary with intimal tacking,⁶ aortic reanastomosis, or patch arterioplasty. Proximal ligation of the anomalous coronary with distal bypass grafting is also used but is limited by durability of bypass grafts.⁴

Coronary unroofing with intimal tacking is the currently favored method for correcting an anomalous aortic origin of the left main coronary artery or right coronary artery from the contralateral sinus. After cardiopulmonary bypass grafting is begun, care must be taken when dissecting the aorta from the main pulmonary artery because the aberrant artery may be injured during this dissection. After establishment of cardioplegic arrest, an oblique aortotomy is generally used, but a “hockey-stick” (vertical followed by oblique) aortotomy may be used if there is uncertainty about the course of the aberrant artery to avoid injury. Upon identifying the abnormal origin, a coronary probe is placed in the artery to confirm its course. With the probe in the arterial lumen, the artery is unroofed, using the probe to prevent inadvertent back wall injury. The edges of the unroofed segment are then tacked to the aortic wall with interrupted fine polypropylene suture, thereby creating a new ostium in a more anatomic position (Fig. 94-3).

FIGURE 94-1 ■ Anomalous origin of the left circumflex (LCX) from the right coronary artery (RCA) in (A) the shallow right anterior oblique, and (B) the right anterior oblique projections.

Anomalous Pulmonary Origin of Coronary Arteries

Anomalous Left Main Coronary Artery from the Pulmonary Artery

Anomalous left main coronary artery from the pulmonary artery (ALCAPA) has an incidence of 0.25% to 0.5% and remains one of the most common etiologies of myocardial ischemia in pediatric patients.⁷ Symptoms will generally present during infancy unless patients have extensive collateralization from the right coronary

artery, in which case symptoms may not present until adulthood. Because they are dependent upon time of diagnosis, symptoms may be related to angina pectoris or heart failure if extensive myocardial infarction has occurred. Diagnosis can be made with echocardiography

FIGURE 94-2 ■ Anomalous origin of the right coronary artery (arrows) from the left cusp high in the aorta above the left main origin.

with color flow, and if the diagnosis remains in question, magnetic resonance angiography or computed tomographic angiography can be used. Once diagnosis is established, surgical correction should be undertaken because of the risk for infarction and sudden death.⁸ The currently favored surgical approach to correction is that described by Neches,⁹ in which a cuff of pulmonary artery is taken around the coronary and used to reimplant the coronary artery to the aorta. If the anomalous coronary has previously been ligated, or if it cannot be sufficiently mobilized for reimplantation, bypass grafting may be undertaken. Although a certain degree of mitral regurgitation may be present from the prior ischemia, or the ventricular wall may be aneurysmal from prior infarction, most clinicians do not advocate valve repair or aneurysm resection at the time of revascularization because functional improvement is usually seen.⁴

Other Anomalous Pulmonary Origins of Coronary Arteries

As described before, ALCAPA is the most common anomalous pulmonary origin of a coronary artery, with the remainder designated as anomalous pulmonary origins of coronary arteries (APOCA). Anomalous right coronary artery from the pulmonary artery is found in 0.002% of the population and is most commonly discovered before the age of 18.¹⁰ The additional types of APOCA reported include anomalous origin of the circumflex coronary artery from the pulmonary artery and anomalous origin of the right and left coronaries from the pulmonary artery, the latter of which is fatal in the neonatal period. Although patients will commonly present with an asymptomatic murmur, symptoms secondary to myocardial ischemia and heart failure have also been reported.⁴ Diagnosis can be made with echocardiography. When the diagnosis is made, most clinicians

FIGURE 94-3 ■ Anomalous origin of the right coronary artery from the left cusp (A) as seen after aortotomy, (B) unroofing of the anomalous coronary artery, and (C) edge plication for creation of a “neo” ostium. (Courtesy Stephen J. Huddleston, MD, PhD.)

advocate aortic reimplantation of the anomalous coronary because of the risk of sudden death if left uncorrected.^{4,10}

Single Coronary Artery

Single coronary artery is an extremely rare coronary anomaly, with an incidence ranging from 0.002% to 0.06%, and is associated with other congenital heart defects in as much as 40% of patients.¹¹⁻¹³ The anomaly can be classified into three types: type 1 describes a single artery supplying the entire heart, type 2 describes a single artery that divides into a right and left coronary artery, and type 3 covers all other variations. Patients will present either with symptoms related to concomitant congenital defects or with angina. Diagnosis is made with coronary angiography. Although some patients will remain asymptomatic, sudden death has been reported secondary to compression between the great vessels, and concerns over angulation and accelerated atherosclerosis have been reported.¹³ Percutaneous coronary intervention and coronary artery bypass grafting have been used successfully for the treatment of patients with ischemic symptoms, although no guidelines exist for intervention in asymptomatic patients.⁴

Left Main Coronary Artery Atresia

Congenital atresia of the left main coronary artery is quite rare, with only limited case reports found in the literature. The anomaly may present in infancy with rhythm disturbances, syncope, or sudden death, whereas if there is sufficient collateralization from the right coronary artery, patients may not present until adulthood, at which time ischemic symptoms will manifest. Diagnosis is made with echocardiography and coronary angiography, which allow for differentiation from a single coronary artery and ALCAPA. Surgery is recommended at the time of diagnosis and may consist of distal revascularization with coronary artery bypass grafting¹⁴ or reattaching the proximal left main coronary artery to the aortic sinuses.¹⁵

High Takeoff Coronary Ostia

The left main and right coronary arteries generally originate from their respective sinuses of Valsalva below the sinotubular junction. Although the incidence varies significantly between series, the coronary arteries may be located significantly above the sinotubular junction in 0.01% to 0.8% of patients.^{16,17} The origin will generally occur within 1 to 2 cm of the sinotubular junction but has been reported to be as high as 5 cm above the sinotubular junction. The clinical significance of this anomaly remains controversial because cases of sudden death with this condition have been reported in patients with concomitant coronary pathology, which may have been responsible for the mortality.¹⁷ In the asymptomatic patient with an isolated high takeoff coronary in whom an incidental finding is made, observation may be warranted.

Coronary Artery Fistula

Coronary artery fistulae may be congenital or acquired, with an incidence ranging from 0.2% to 0.85%.¹⁸ The fistulae consist of a direct precapillary communication between a major coronary artery and a cardiac chamber, a major vessel, or a vein. When drainage occurs into a cardiac chamber, the term *coronary-cameral fistula* may be used. Currently, approximately two thirds of coronary artery fistulae are congenital and may be associated with additional congenital heart defects in one third of patients.¹⁹ These are thought to develop because of the persistence of sinusoidal connections between the lumens of the tubular heart in early development.²⁰ Acquired fistulae may develop after trauma, coronary angiography or other catheter-based intervention, myocardial biopsy, vasculitis, or cardiac surgery. Most commonly, fistulae will be single in approximately 80% of cases, with multiple fistulae occurring in 10% to 15% of patients, and dual right-left coronary fistulae occurring in less than 10% of patients.²⁰ The left anterior descending and right coronary arteries are the most common sites of origin for fistulae, with the circumflex being an infrequent site.⁴ Drainage runs into the low-pressure right heart or pulmonary artery in greater than 90% of cases but may rarely run into the left atrium or ventricle. Fistulae may be classified as type A or type B based on the system proposed by Sakakibara and colleagues.²¹ In type A fistulae, the coronary artery proximal to the fistula site is dilated, whereas in type B, the coronary is dilated over its entire length, terminating in the right heart. This distinction is of significance clinically because type A fistulae may be ligated on the epicardial surface of the heart, whereas type B should be ligated intracamerally. If fistulae are large, symptoms may appear during childhood, with angina and dyspnea being the most common complaints. Echocardiography is able to identify a fistula, but catheterization is required for surgical planning and obtaining hemodynamic measurements. Although fistulae rarely close spontaneously, intervention (catheter-based or surgical) is favored by most clinicians in younger patients, even if they are asymptomatic, to prevent complications such as ischemia, endocarditis, aneurysm, or pulmonary hypertension.⁴ No consensus exists for the management of asymptomatic older patients with incidentally discovered small fistulae, but observation may be appropriate.²² Successful catheter-based interventions include stenting or coiling and have not been compared with surgical techniques. Surgical techniques are varied and may be performed with or without the use of cardiopulmonary bypass (dependent upon technique). If the coronary artery can be mobilized on the epicardial surface, the fistula may be ligated without the use of cardiopulmonary bypass. Pledgeted mattress sutures may be passed deep into the artery to occlude the fistula without the use of bypass. Internal closure can be performed via arteriotomy if the patient can tolerate temporary proximal and distal occlusion of the coronary artery. Alternatively, the coronary artery may be ligated both proximally and distally with bypass grafting to preserve distal perfusion. Closure can be performed from within

the draining chamber with a purse-string suture or patch, both of which require cardiopulmonary bypass.²⁰

Muscle Bridge

The “epicardial” coronary arteries are normally located superficially on the epicardial surface of the heart, but in certain patients they may course through the myocardium for varying lengths, with the overlying muscle termed a *bridge*. Although there exists debate regarding the contribution of muscle bridges to myocardial ischemia,²³ multiple reports demonstrate ischemia secondary to systolic narrowing of the coronary artery from the overlying muscle.²⁴ In addition to the direct mechanical effects of the bridge, there may be some increase in progression of atherosclerosis proximal to the bridge, which may also contribute to ischemia. The incidence of muscle bridging varies tremendously, from 0.5% to 85%, and is dependent upon the type of study done (angiography versus computed tomography versus autopsy),^{4,24} but muscle bridging with arterial compression is seen in only approximately 0.5% of patients undergoing coronary angiography for evaluation of chest pain.²⁴ If muscle bridging is suspected, coronary angiography with intravascular ultrasonography should be used to confirm the diagnosis (Fig. 94-4). Although some degree of vessel compression is likely benign, reduction of the coronary diameter by greater than 70% during systole and 35% during diastole suggests significant coronary compression.²⁵ Medical management remains the first-line treatment for symptomatic muscle bridging and consists primarily of beta blockade. Via reducing heart rate and prolonging diastole, beta blockers are able to reduce compression and improve flow.²⁶ Calcium channel blockers and nitrates may also provide some relief if vasospasm is a concern.²⁴ For symptoms refractory to medical management, percutaneous coronary intervention with stenting or surgery may be offered. Coronary stenting with drug-eluting stents has demonstrated favorable midterm results, but long-term data are pending.²⁴ Surgical options for failure of medical management include supra-arterial myotomy or coronary artery bypass grafting. Supra-arterial myotomy has yielded good long-term results, but care must be taken to avoid entry into the right ventricle, which may be vulnerable during unroofing.²⁷ As an alternative to myotomy, coronary artery bypass distal to the

muscle bridge may also be considered for patients with atherosclerotic disease proximal to the bridge and in patients with a thick muscle bridge, because this may increase the risk of inadvertent coronary injury or ventricular entry.

Coronary Aneurysms (Coronary Artery Ectasia and Dilating Coronary Atherosclerosis)

Aneurysms of the coronary artery, defined as a diameter 1.5 times the adjacent normal coronary artery, have been reported to occur in 1.5% to 4.9% of the population.^{28,29} Aneurysms are most commonly secondary to underlying atherosclerotic disease but may be congenital or occur secondary to infection, inflammatory disease/vasculitis, or trauma (including iatrogenic trauma after percutaneous intervention). Morphologically, the aneurysms are termed *saccular* or *fusiform*, the latter of which are more commonly seen in patients with atherosclerotic disease. Although fusiform aneurysms are more common, the saccular type is more prone to complications such as rupture or thrombosis. Approximately 50% of coronary artery aneurysms are found in the right coronary artery, with approximately 25% to 50% found in the left anterior descending or left circumflex arteries, and fewer than 10% are found in the left main coronary artery.^{29,30} Diagnosis is generally made during evaluation for ischemic complaints. Although echocardiography may demonstrate the aneurysm, coronary angiography remains the definitive diagnostic modality. There is currently no consensus for the treatment of coronary artery aneurysms among medical management, percutaneous intervention with covered stents, and coronary artery bypass grafting. Medical management entails therapy for the underlying pathology (standard management of atherosclerotic coronary disease, clearance of infection, and immunosuppression in the case of vasculitis). Use of statins to inhibit matrix metalloproteinase activity and use of angiotensin II receptor blockers to inhibit transforming growth factor- β have been tried as adjunct therapy to standard medical management, but no data exist regarding their benefit.³¹ Larger aneurysms may benefit from antiplatelet therapy or formal anticoagulation to reduce the risk of thrombosis and embolization, although size criteria and

FIGURE 94-4 ■ Muscle bridge (arrows) causing compression during systole.

level of anticoagulation have not yet been determined.³² The successful use of covered stents has been reported (Fig. 94-5), but concerns persist about the risk of stent thrombosis.³¹ Indications for surgical intervention include standard indications for coronary artery bypass grafting, aneurysms near large-branch bifurcations, distal embolization with resulting myocardial ischemia, progressive enlargement, left main coronary artery aneurysms, and size threefold the normal coronary diameter.^{33,34} Methods for the repair of saccular aneurysms include lateral aneurysmorrhaphy, endarterectomy, and thrombectomy. Fusiform aneurysms are surgically managed with conventional distal bypass grafting and aneurysm ligation.

MECHANICAL INJURY TO THE CORONARY ARTERY

Coronary Artery Embolization

The coronary arteries are partially protected from embolic occlusion by the acute angulation of the coronary ostia relative to aortic outflow and by protection from the aortic valve leaflets during systole. Coronary embolization may be iatrogenically induced during catheter-based interventions (transcatheter aortic valve replacement, coronary angiography) or during cardiac surgery (dislodged thrombus, vegetation, calcium, fat, or

FIGURE 94-5 ■ Right coronary artery pseudoaneurysm (arrow) in (A) the right anterior oblique projection and (B) the left lateral projection. (C) Deployment of a balloon-expandable, covered stent with (D) aneurysm exclusion.

adhesive/hemostatic compounds). Noniatrogenic causes of coronary embolization include intracardiac or valvular thrombus, tumor, vegetation secondary to endocarditis, or paradoxical emboli in the presence of right-to-left shunting. The clinical consequences of coronary embolization are based on size and location. Most commonly, the left anterior descending coronary artery is affected.³⁵ Larger emboli may result in significant myocardial ischemia and require intervention. Coronary angiography will often demonstrate an abrupt cut-off point to contrast flow. Percutaneous attempts to restore flow are the mainstay of therapy during diagnostic angiography with bypass surgery or embolectomy reserved for patients in whom percutaneous attempts are unsuccessful with ongoing significant ischemia. For patients who have coronary embolization during surgery, which is identified in the operating room, attempts at clearance via administration of retrograde flushing via the coronary sinus, embolectomy, or bypass graft may be attempted to relieve ischemia.

Coronary Artery Dissection

Coronary artery dissection is defined as separation of the media of the coronary artery with or without an intimal tear. The resulting hemorrhage in the coronary arterial wall can result in luminal narrowing and subsequent ischemia. A dissection is termed *primary* when it occurs spontaneously, or *secondary* when it is caused by an aortic dissection, trauma, or iatrogenic intervention.³⁶ The dissection can be graded into types A through F based on a National Heart, Lung and Blood Institute classification system.³⁷ Type A includes radiolucent areas within the coronary artery during contrast injection, which do not persist after the clearance of dye. Type B dissections appear as a double lumen separated by a radiolucent area, which resolves after clearance of dye. Type C appears as contrast outside of the coronary lumen, with persistence after dye clearance. Type D appears as a spiral lesion with persistence of contrast dye. Type E appears as persistent filling defects, and type F appears as total vessel occlusion without antegrade flow.

Spontaneous Coronary Artery Dissection

The reported incidence of spontaneous coronary artery dissection varies widely from 0.2% to 1.1% in patients undergoing coronary angiography.^{36,38} The mean age at presentation ranges from 30 to 45 years old, with greater than two thirds of patients being women. Notably, approximately one third of female patients will present in the peripartum period. The left anterior descending coronary artery is most frequently dissected in women, and the right coronary artery in men.³⁹ The underlying etiology may be related to atherosclerosis, peripartum vascular changes, connective tissue disorders, or vasculitis. The diagnosis is most commonly made with conventional coronary angiography with or without the use of intravascular ultrasonography or optical coherence tomography, although computed tomographic angiography is becoming more widely used for diagnosis and follow-up.⁴⁰ Although no specific guidelines exist for the management of spontaneous coronary artery dissection,

medical management (e.g., antithrombotic therapy, anti-ischemic therapy with beta blockers and nitrates), percutaneous coronary intervention, and coronary artery bypass grafting have all been used. In hemodynamically stable patients with no evidence of ongoing ischemia, medical management may be considered.³⁶ In patients with ischemia, the decision to perform percutaneous intervention versus coronary artery bypass grafting should be based on anatomy. Single-vessel dissections may be managed with stenting, if possible. Left main coronary artery and multivessel dissections, as well as failed percutaneous intervention cases, should be managed with conventional coronary artery bypass grafting.^{36,38}

Coronary Artery Trauma

Blunt Trauma

Coronary injury secondary to blunt trauma is rare, accounting for less than 2% of injuries in patients presenting after blunt chest injury.⁴¹ The mechanism of injury may be secondary to aortic dissection with retrograde involvement of the coronary ostia, proximal coronary avulsion (partial or complete) from the aortic root, or intimal injury with resulting coronary dissection or thrombosis. The left anterior descending and right coronary arteries are the most commonly injured. Clinical manifestations are generally immediate with resulting hemodynamic compromise from myocardial ischemia or tamponade, but some injuries may result in delayed thrombosis with late presentation. In clinically unstable patients with bleeding, immediate exploration is warranted with concomitant coronary artery bypass if the injury is proximal, whereas in patients without bleeding, coronary angiography with intervention may be done.^{42,43}

Penetrating Trauma

Owing to their anatomic location, the left anterior descending and right coronary arteries are the most commonly injured after penetrating chest trauma. The immediate clinical manifestation is generally pericardial tamponade. Penetrating injury with hemodynamic compromise or evidence of pericardial fluid will mandate operative exploration. Small coronary artery branches and the distal third of large epicardial coronary arteries may be ligated without inducing significant ventricular dysfunction, but postoperative arrhythmias may occur as a result of focal infarction. For more proximal coronary arterial injuries, intracoronary shunts may be used to gain temporary control of bleeding. Because many penetrating injuries are anterior, off-pump coronary artery bypass techniques with limited heparinization may be done to primarily repair, vein-patch repair, or perform bypass grafting. Standard on-pump techniques can be used as well if exposure is poor or ventricular function is compromised.^{42,43}

Iatrogenic Coronary Artery Trauma

Coronary artery dissection or thrombosis is exceedingly rare after coronary angiography, with rates of less than

0.01%.⁴⁴ These complications can often be managed percutaneously with intracoronary stenting but may require emergent coronary artery bypass grafting if there is resulting ischemia. During cardiac surgery, coronary injuries such as dissection may occur secondary to coronary intubation with handheld cardioplegia cannulae, or use of intracoronary probes. Inadvertent coronary ligation secondary to misplaced sutures during repair of ventricular injuries can occur. Often these injuries will manifest as ventricular dysfunction during separation from cardiopulmonary bypass and necessitate distal bypass grafting.

PROGRESSIVE NONATHEROSCLEROTIC CORONARY OCCLUSIVE DISEASE

Coronary Artery Vasculitis

Polyarteritis Nodosa

Polyarteritis nodosa is a systemic necrotizing vasculitis affecting medium and small arteries. The overall incidence of polyarteritis nodosa is low, with estimates between 0.4 and 2 per million per year.⁴⁵ The vasculitis most commonly affects the kidneys, gastrointestinal tract, skin, joints, and muscles, with symptomatic coronary involvement reported less frequently. The average age of symptom onset ranges from 30 to 50 years, with a predominance in males. Coronary involvement can result in premature atherosclerosis, coronary aneurysm, dissection, or thrombosis.⁴⁶ Medical management of the vasculitis centers on immunosuppression with glucocorticoids and antiplatelet therapy with aspirin. For patients in whom coronary complications develop, the role of surgery versus percutaneous coronary intervention remains to be defined. Most reports indicate that patients are treated with percutaneous intervention initially, with surgery as an option if the former fails. Coronary artery bypass grafting in this patient population is complicated by immunosuppression and concerns with healing, operating during active inflammation, and selection of an appropriate conduit, given concerns of internal mammary artery involvement in some cases of polyarteritis nodosa.^{47,48} Given the generally young age at presentation, some clinicians recommend preoperative imaging of the internal mammary arteries and subsequent use as a conduit if suitable, but they favor avoiding the radial artery as a conduit because of the risk of disease involvement.⁴⁷

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an immune-mediated inflammatory disease with primarily musculoskeletal and mucocutaneous inflammation and predominance in females. When matched against controls with similar risk factors for coronary artery disease, patients with SLE have a threefold higher risk of subclinical coronary artery disease and present at earlier ages, which may be attributable to chronic inflammation, a prothrombotic state, or chronic use of corticosteroids.⁴⁹ When myocardial ischemia is suspected, coronary angiography should be undertaken, with indications for

percutaneous intervention versus coronary artery bypass grafting remaining the same as for patients without SLE. If coronary artery bypass grafting is planned, perioperative consideration of concomitant valvular disease and hypercoagulability should be made. Valvular heart disease is the most common cardiac abnormality seen in patients with SLE, with an incidence of 13% to 100% found in autopsy studies, and is a leading cause of morbidity.⁵⁰ Left-sided valve involvement predominates, and all patients should undergo preoperative echocardiography before revascularization to aid in surgical planning.⁴⁹ Limited case series have reported on the success of coronary artery bypass grafting in patients with SLE and have noted no inflammatory involvement of the left internal mammary artery on pathology specimens, suggesting its suitability for conduit use.^{51,52}

Wegener Granulomatosis

Wegener granulomatosis is a necrotizing vasculitis affecting medium and small vessels, most commonly in the respiratory tract and kidneys. Coronary involvement most commonly manifests as arteritis,⁵³ but clinically significant coronary arterial involvement is extremely rare.⁵⁴

Takayasu Disease

Takayasu arteritis is predominantly a disease found in young Asian women between 10 and 50 years of age and in which the vasculitis affects the aorta and its major branches. The incidence of coronary arterial involvement complicating the arteritis has been reported to be approximately 10%.⁵⁵ Proximal coronary arterial involvement is common, increasing the risk for severe myocardial ischemia.⁵⁶ Reports of percutaneous management of coronary arterial disease have met with limited long-term success,⁵⁷ but use of drug-eluting stents may provide some increase in long-term patency.⁵⁸ Given the limited data on long-term patency rates with percutaneous intervention, and the incidence of left main coronary arterial involvement, coronary artery bypass grafting is often considered a potential initial treatment option. Undertaking coronary artery bypass grafting is complicated by the chronic inflammation of the entire aortic wall, which can lead to morbidity from manipulation, clamping, and creation of proximal anastomoses, as well as subclavian arterial involvement, which can limit usability of the internal mammary arteries.⁵⁹ Successful series have reported using an off-pump technique limiting aortic manipulation and using other arterial conduits such as the gastroepiploic artery.⁵⁹ If the clinical situation allows, surgery should be delayed until inflammation can be controlled with immunosuppressive agents by following serological inflammatory markers. Postoperatively, patients require close long-term follow-up because of the risk of anastomotic aneurysm formation.⁶⁰

Mucocutaneous Lymph Node Syndrome (Kawasaki Disease)

Initially described in 1967, mucocutaneous lymph node syndrome, otherwise known as Kawasaki disease, is a

systemic vasculitis most commonly seen in children that can lead to coronary artery aneurysm formation (Fig. 94-6), thrombosis, or stenosis from scarring. In Japan, the incidence is as high as 175 per 100,000, whereas in the United States, the incidence is 19 per 100,000.⁶¹ Although aneurysms may form in as much as 20% of patients, surgery is relatively uncommon because aneurysms may regress over time.⁶² In Japan, coronary artery bypass grafting is performed in 0.3% to 0.5% of patients diagnosed with Kawasaki disease.^{63,64} The left main coronary artery is the most frequently involved, followed by the left anterior descending artery, the right coronary artery, and the left circumflex artery.⁶⁵ Aneurysm formation may occur within the 6 to 8 weeks after onset of symptoms,

FIGURE 94-6 ■ Coronary dilation in Kawasaki disease seen in (A) the left coronary system and (B) the right coronary system.

and as much as 50% of cases will resolve within 5 years with appropriate medical management, with less than 5% progressing to chronic obstructive coronary artery disease.⁶¹ When intervention is required for ischemia or large aneurysm size, coronary artery bypass grafting is favored over percutaneous coronary intervention because of the long-term patency issues with percutaneous intervention,⁶⁶ and the use of internal mammary artery grafts are favored because of their long-term patency.⁶³

Intimal Proliferation and Fibrosis

Fibrous hyperplasia of the coronary arteries is extremely rare, with only limited case reports published. Disease is most often limited to the intima. Although there is a predominance in females, the etiology remains unknown but is thought to be secondary to genetic, hormonal, or mechanical factors. Fibrous hyperplasia of the coronary arteries can result in sudden death thought to be secondary to arrhythmia.⁶⁷

Ionizing Radiation

Thoracic irradiation is commonly used for the treatment of Hodgkin disease, breast cancer, and certain lung cancers. Patients with a history of thoracic irradiation are at higher risk for the development of atherosclerotic and nonatherosclerotic coronary stenosis secondary to endothelial injury at the time of treatment, and subsequent development of plaques, which may be limited to the intima and independent of cholesterol deposition.^{68,69}

These patients may present at younger ages, often in the second and third decade after treatment. Indications for revascularization in this patient subset are the same as for other patients with obstructive coronary artery disease, but several considerations should be made before percutaneous intervention or coronary artery bypass grafting is considered. Although data are limited for drug-eluting stents, bare metal stenting and balloon angioplasty have been associated with significantly higher rates of restenosis relative to patients without a history of irradiation.⁷⁰ If surgery is planned, consideration should be given to radiation-induced damage to the skin, which may impair healing; mediastinal fibrosis, which may add difficulty to sternal entry; concomitant pericardial disease, which may add difficulty in identifying epicardial coronary arterial targets; and radiation injury to the internal mammary artery, which may preclude its use as a conduit.⁶⁹

Cardiac Transplantation

Cardiac allograft coronary disease secondary to vasculopathy is the leading cause of late mortality in transplant recipients, with greater than 40% of recipients demonstrating coronary disease 8 years after transplantation.⁷¹ Angina is absent secondary to denervation during implantation; therefore, screening is essential for detection. Current screening protocols use coronary angiography with intravascular ultrasonography to establish diagnosis.⁷² The vasculopathy often results in diffuse disease limiting the role for intervention, but in selected cases percutaneous coronary intervention and coronary artery

bypass grafting have been used successfully, but survival benefits remain to be proven.⁷³ Retransplantation remains the only definitive treatment for chronic allograft vasculopathy.⁷²

Extrinsic Coronary Artery Compression

Compression of the epicardial coronary arteries from adjacent structures, tumor, or abscess may result in myocardial ischemia. The most common adjacent structures to cause extrinsic compression are the pulmonary artery in the setting of pulmonary hypertension, and aortic root/sinus of Valsalva aneurysms. Symptoms will most commonly be angina-related. Contrast-enhanced computed tomography of the chest can raise the clinical suspicion of extrinsic coronary artery compression, but coronary catheterization with intravascular ultrasonography has been advocated as the gold standard for diagnosis.⁷⁴ Aneurysm repair and abscess drainage are indicated in the setting of aneurysms and infection, respectively, whereas in the setting of coronary compression secondary to pulmonary arterial hypertension, management options include coronary stenting or bypass grafting.

SUBSTANCE ABUSE

Chest pain has been reported in as much as 40% of patients who present to the emergency department after cocaine use.⁷⁵ A small subset of these patients, ranging from 0.7% to 6%, will have myocardial ischemia and/or infarction.^{76,77} The etiology of the ischemia is multifactorial, secondary to increases in myocardial oxygen demand, vasoconstriction, and increased propensity for thrombosis.⁷⁸ Beyond the acute complications of cocaine use, studies suggest that cocaine users do not have an increased propensity of angiographically significant coronary artery disease when adjustments are made for other atherosclerotic risk factors.⁷⁹

Initial treatment of patients with suspected cocaine-induced ischemia should be similar to all patients with myocardial ischemia. For patients undergoing percutaneous coronary intervention, consideration should be given to the use of bare metal stents over drug-eluting stents secondary to concerns over compliance with antiplatelet agents.⁷⁸ Although there are no specific guidelines for surgical management of cocaine-associated and/or -induced myocardial infarction, coronary artery bypass grafting should be considered in cases of multivessel disease, coronary dissection, or coronary thrombosis not amenable to treatment with percutaneous intervention.

THE PERICARDIUM

History

The earliest descriptions of the pericardium date back to Hippocrates (460 to 377 BC).¹ Galen (AD 129 to 210) described the protective function of the pericardium and also reported a pericardial effusion in animals. Avenzoar (1091 to 1162) described pericarditis,² and Vesalius (1514 to 1564) carefully documented the anatomy of the pericardium. Jean Riolan (1649) suggested treating pericarditis with trephination of the sternum, and a case of hemopericardium was reported by William Harvey

(1649). The conditions of cardiac tamponade and constrictive pericarditis were described by Richard Lower (1669), John Mayow (1674), and Morgagni (1756). The pathophysiology of constrictive pericarditis was further clarified by Cheevers in 1842.

Kussmaul (1873) noted the association between constrictive pericarditis and decreased intensity of the peripheral pulse (now termed *pulsus paradoxus*). Kussmaul also described inspiratory jugular venous distention, now termed *Kussmaul sign* (as opposed to *normal inspiratory jugular venous collapse*). Pick (1896) reported three patients with constrictive pericarditis and hepatic cirrhosis (a condition now known as *Pick cirrhosis*).

The first successful pericardiotomy was performed by Romero in 1819, and the first pericardiocentesis was performed by Franz Schuh in 1840. Pericardial resection for constrictive pericarditis was proposed by Weill (1895) and Delorme (1898), with pericardiectomy ultimately performed by Rehn (1913) and Sauerbruch (1925). Early surgical treatment of constrictive pericarditis in the United States was reported by Beck (1930), Churchill (1936), and Blalock (1937). Radical pericardiectomy, including excision of thickened epicardium when necessary, was advocated by Holman (1955).

Anatomy

The pericardium is a fibrous sac surrounding the heart and mediastinal great vessels. The outer wall of the pericardial sac consists of an outer fibrosa and an inner serosa.³ Histologically, the fibrosa is fibro-collagenous tissue with elastic fibers oriented along the lines of stress, and the pericardial serosa is composed of mesothelial cells with microvilli and an underlying basal lamina.³

This outer pericardial sac folds onto the heart and great vessels, where the epicardium and outer adventitial layer of the heart and great vessels constitute the visceral lining of the pericardial sac. Laterally, the pericardium forms the medial walls of the pleural spaces. Inferiorly, the pericardium is the superior surface of the central tendon of the diaphragm, and, superiorly, the pericardium blends with the deep cervical fascia. Anteriorly, the pericardium is loosely joined to the xiphoid process and the sternal manubrium by ligamentous structures. Posteriorly and superiorly, the pericardium envelops the great vessels, the venae cavae, and the pulmonary veins. The posterior pericardial space has two developmental

recesses: the transverse sinus separating the great vessels from the pulmonary veins and the oblique sinus separating the left and right pulmonary veins (Fig. 95-1).³

The arterial blood supply and venous drainage of the pericardium come from the pericardiophrenic branches of the internal mammary vessels bilaterally. The lymphatic drainage of the visceral pericardium is the tracheal and bronchial lymph chain, and the parietal pericardium shares lymphatic drainage with the sternum, diaphragm, and mid mediastinum. The pericardium is innervated from the phrenic nerves, with some vagal innervation via the esophageal plexus.³

The pericardium normally contains 15 to 35 mL of serous fluid. Pericardial fluid is a transudate containing less protein but more albumin than serum; therefore, pericardial fluid has a lower osmolality than does plasma.³

Normal Physiology

The pericardium and pericardial fluid minimize friction and energy loss during cardiac motion. While doing so, the normal pericardium and its external attachments maintain cardiac position within the mediastinum in the presence of gravitational or other forces that could impair cardiac filling or function. The pericardium also serves as a barrier, protecting the heart from inflammation or malignancy in adjacent structures.

The normal pericardium has mechanoreceptors connected to phrenic nerve and vagal nerve afferents, which (with stimulation) lower blood pressure, slow heart rate, and contract the spleen in dogs. Pericardial fluid contains prostacyclin, which can affect coronary artery vasomotor tone, and it has fibrinolytic properties that can lyse intra-pericardial clot.

FIGURE 95-1 ■ Anatomy of the posterior pericardial reflections. Note the transverse sinus and the oblique sinus. (From Spodick DH: *The pericardium*, New York, 1997, Marcel Dekker.)

At rest, the normal pericardium probably has little restraining effect on cardiac systolic or diastolic function.⁴ However, under conditions of acute cardiac dilation, the normal pericardium probably increases diastolic stiffness and limits diastolic filling of the left and right ventricles.⁵ Under normal conditions, relatively little interaction between the left and right ventricles is mediated by the pericardium.⁶

Normal pericardial pressure at end expiration is -2 mm Hg. Like pleural pressure, pericardial pressure decreases during inspiration and increases during expiration. As a result, inspiration normally decreases left ventricular stroke volume and decreases aortic blood pressure by less than 10 mm Hg. The mechanisms for these effects do not require an intact pericardium and are similar to the mechanisms of pulsus paradoxus (see later).

Pathophysiology

Pericardial Effusion

Pericardial effusion (>50 to 100 mL) is the simple result of more fluid transuding into the pericardial space than is resorbed. Pericardial effusions requiring drainage typically contain 500 to 700 mL of fluid. Eventually, pericardial pressure rises high enough that resorption matches fluid production. Sustained increases in pericardial pressure over time cause the pericardial sac to stretch (because of material plasticity, or creep) with slippage of pericardial collagen fibers and pericardial thinning. Causes of increased pericardial fluid production include inflammation or infection of the pericardium. Decreased pericardial fluid resorption can result from venous hypertension or lymphatic obstruction. If pericardial effusion increases pericardial pressure sufficiently, cardiac tamponade and pulsus paradoxus can result (see later).

Cardiac Tamponade

Cardiac tamponade has been defined as hemodynamically significant cardiac compression from accumulating pericardial contents that evoke and defeat compensatory mechanisms.³ Cardiac tamponade can result from pericardial fluid, pus, blood, air, or tumor. In a normal pericardium, approximately 200 mL of acute pericardial fluid accumulation can produce tamponade, but larger volumes may be required in chronically enlarged pericardial sacs.

The initial effect of cardiac tamponade is decreased venous return to the right heart resulting from a direct pressure effect and from effectively decreased right atrial and right ventricular diastolic compliance. Decreased right ventricular filling decreases stroke volume and thus cardiac output. Pulmonary venous return to the left heart is decreased by increased left atrial pressure and by decreased right ventricular output. Central venous pressures of 14 to 30 mm Hg are typically associated with cardiac tamponade in euolemic individuals, and lower venous pressures can occur with cardiac tamponade if hypovolemia is also present.

Left ventricular diastolic compliance and diastolic filling are also impaired by cardiac tamponade. Increased

BOX 95-1 Diagnostic Signs of Cardiac Tamponade

PHYSICAL EXAMINATION

- Pulsus paradoxus

PULMONARY ARTERY CATHETER FINDINGS

- Central venous pressure > 14 mm Hg
- Near equalization of central venous, pulmonary artery, and capillary wedge pressures in diastole
- Decreased cardiac output

ECHOCARDIOGRAPHY

- Right atrial compression
- Right ventricular diastolic collapse
- Inferior vena caval dilation
- Inspiratory shift of interventricular septum leftward
- Inspiratory flow velocities: $\uparrow$ tricuspid and pulmonic, $\downarrow$ mitral and aortic

diastolic right ventricular pressure relative to left ventricular diastolic pressure can shift the interventricular septum leftward, thus decreasing preload of the interventricular septum and effectively decreasing left ventricular contractility. By combining these mechanisms, inspiration with cardiac tamponade can decrease systolic blood pressure by greater than 10 mm Hg (see [Pulsus Paradoxus](#), next). Eventually, arterial hypotension and increased intrapericardial pressure can decrease coronary perfusion sufficiently to decrease cardiac contractility caused by global cardiac ischemia.

Diagnostic signs of cardiac tamponade are listed in [Box 95-1](#).

Pulsus Paradoxus

Cardiac tamponade is associated with pulsus paradoxus, which is defined as a fall in systolic blood pressure of greater than 10 mm Hg with inspiration. Pulsus paradoxus is thus an exaggeration of the normal inspiratory decrease in systolic blood pressure because of the same mechanisms (see [Normal Physiology](#), earlier). Although pulsus paradoxus is characteristic of cardiac tamponade, pulsus paradoxus can also be seen in chronic obstructive pulmonary disease, pulmonary embolism, obesity, right heart failure, and ascites, where it occurs by the same mechanisms.⁶ Pulsus paradoxus may be absent in cardiac tamponade with severe left ventricular dysfunction, atrial septal defect, severe aortic regurgitation, or positive pressure breathing.³ Proposed mechanisms of pulsus paradoxus include the following:

- Pooling of blood in the lungs during inspiration
- Increased right ventricular filling during inspiration resulting from lower right ventricular pressure (in turn, right ventricular distention may shift the interventricular septum leftward, thus decreasing septal muscle preload and decreasing left ventricular stroke volume)⁷
- Increased left ventricular afterload (aortic pressure minus pericardial pressure), which decreases left ventricular stroke work⁸

Constrictive Pericarditis

Constrictive pericarditis results when the volume of the pericardial sac itself is sufficiently reduced relative to cardiac volume that cardiac filling is impaired. In constrictive pericarditis, pericardial fluid is generally absent or of normal volume. The wall of the pericardial sac is usually thickened in constrictive pericarditis and may be 3 to 20 mm thick, as opposed to the 1- to 2-mm thickness of normal pericardium (Box 95-2).

Unlike cardiac tamponade, constrictive pericarditis impairs cardiac filling only in late diastole. Thus, early diastolic filling of the right ventricle occurs briefly in constrictive pericarditis until the ventricle suddenly reaches the rigid constraint of the pericardium. The result is the pathognomonic “square root” sign in the right and left ventricular diastolic filling pressure waveforms (Fig. 95-2).

Similarly, in constrictive pericarditis, the central venous pressure tracing has a prominent *y* descent that corresponds to the initial dip of the square root sign of the right and left ventricular tracings. This *y* descent normally results from “diastolic collapse” of the normal venous pressure as rapid atrial filling occurs, and the *y* descent is exaggerated by constrictive pericarditis. Constrictive pericarditis impairs reservoir function and contractile function of the left atrium.⁹ Constrictive pericarditis also selectively impairs contractile function in the left and right ventricular free walls relative to that of the interventricular septum on magnetic resonance imaging.¹⁰

Constrictive pericarditis is associated with inspiratory jugular venous distention (Kussmaul sign; see Fig. 95-2), which is less frequent in cardiac tamponade. Kussmaul sign can also occur in right ventricular failure, restrictive cardiomyopathy, cor pulmonale, and acute pulmonary embolism.

BOX 95-2 Diagnostic Signs of Constrictive Pericarditis

PHYSICAL EXAMINATION

- Kussmaul sign

PULMONARY ARTERY CATHETER FINDINGS

- Central venous pressure > 14 mm Hg
- Near equalization of central venous, pulmonary artery, and capillary wedge pressures in diastole
- Decreased cardiac output
- Square root sign in right and left ventricular pressure tracings
- Prominent *y* descent in central venous pressure tracing

ECHOCARDIOGRAPHY, COMPUTED TOMOGRAPHY, OR MAGNETIC RESONANCE IMAGING

- Impaired right and left ventricular free wall strains relative to septal strain
- Pericardial thickening
- Right ventricular diastolic collapse
- Minimal pericardial fluid

Chronic elevation of venous pressures in constrictive pericarditis can result in hepatic congestion, cardiac cirrhosis, protein-losing enteropathy, and nephrotic syndrome. Chronically, constrictive pericarditis alters the neurohormonal axis with elevations of serum norepinephrine, renin, aldosterone, cortisol, growth hormone, and atrial natriuretic peptide.¹¹

The differential diagnosis of constrictive pericarditis consists primarily of restrictive cardiomyopathy, which can occur simultaneously with constrictive pericarditis.^{5,12} Characteristic histology on myocardial biopsy, pulmonary capillary wedge pressure greater than 5 mm Hg greater than central venous pressure, slower early diastolic filling, and impaired left ventricular systolic function all favor restrictive cardiomyopathy over constrictive pericarditis. Acute volume loading of 500 mL during right heart catheterization accentuates the right-sided pressure findings of constrictive pericarditis and produces smaller changes in restrictive cardiomyopathy.

Diagnosis of Pericardial Disease

History and Symptoms

The presenting symptoms of pericardial disease can include fever, malaise, chest discomfort, shortness of breath, pedal edema, and abdominal distention. Medical history may reveal prior chest trauma, chest irradiation, or exposure to infectious agents such as *Mycobacterium tuberculosis*. The time course of pericardial disease is described as *acute* (<3 months), *chronic* (>3 months), or *recurrent*.⁵

Physical Examination

Physical examination of the patient with pericardial disease may reveal findings of fever, tachycardia, or tachypnea. The peripheral arterial pulse may paradoxically diminish during inspiration (pulsus paradoxus). Inspiratory jugular venous distention may be present (Kussmaul sign). Chest examination may show dullness at the lung bases, muffled cardiac sounds, and a pericardial rub or pericardial knock. A prominent S₃ gallop may be present in constrictive pericarditis. Abdominal examination may demonstrate hepatomegaly or ascites, and pedal edema may be present. The extremities may be cool and constricted in tamponade.

Chest Radiograph

The chest radiograph may show cardiomegaly in pericardial effusion. Pericardial calcification can accompany constrictive pericarditis. Pleural effusion may be present in pericardial effusion, pericardial tamponade, and constrictive pericarditis. Chest radiography may also demonstrate pneumopericardium or mediastinal mass resulting from pericardial cyst.

Electrocardiogram

Pericardial disease can be associated with atrial fibrillation, and the electrocardiogram (ECG) may show

FIGURE 95-2 ■ This patient has constrictive pericarditis. **A**, Chest radiograph with cardiomegaly. **B**, Electrocardiogram with low voltage. **C**, Echocardiogram with pericardial thickening (arrow). **D**, Computed tomographic image showing pericardial thickening (arrow). **E**, Simultaneous right ventricular (green) and left ventricular (yellow) pressure tracings with “square root sign” (arrow) and equalization of diastolic right and left ventricular pressures. **F**, Histology of resected pericardium with marked fibrous thickening and inflammation of the parietal surface (top of picture). **G**, Intraoperative finding of thickened pericardium grasped in clamps.

diminished QRS voltage (see Fig. 95-2). The four stages of ECG changes in acute pericarditis are as follows:

- Stage I—ST elevation in all leads except AVR and V₁
- Stage II—Normal ST segments, but T wave flattening
- Stage III—T wave inversion without Q waves or loss of R wave voltage
- Stage IV—Normalization of T wave

Echocardiography

Echocardiography can easily detect loculated or generalized pericardial effusion. An echo-free pericardial space of less than 10 mm is termed a *small effusion*, whereas circumferential spaces of 10 to 20 mm and greater than 20 mm are considered moderate and large pericardial effusions, respectively.^{5,13} The echocardiogram can also be used to diagnose intrapericardial masses, pericardial cysts, pericardial calcification or thickening, or associated cardiac disease. The echocardiogram can be diagnostic of

cardiac tamponade with findings of end-diastolic right atrial collapse, diastolic right ventricular collapse, and inspiratory interventricular septal shift leftward with increased tricuspid and pulmonic flow velocities and decreased mitral and aortic flow velocities, and dilation of the inferior vena cava (Fig. 95-3).^{13,14}

Computed Tomography

Computed tomography (CT) can demonstrate pericardial effusion, pericardial calcification and thickening, intrapericardial masses, and pericardial cysts (see Fig. 95-2). CT may be more sensitive than magnetic resonance imaging (MRI) in detecting calcification, but it has the disadvantages of requiring intravenous contrast injection and having more motion artifact.¹⁵

Magnetic Resonance Imaging

MRI can demonstrate pericardial effusion, pericardial thickening, intrapericardial masses, pericardial cysts, and

FIGURE 95-3 ■ Two-dimensional echocardiogram (parasternal long-axis view) showing pericardial effusion (yellow arrows) and cardiac tamponade with collapse of the right ventricle (RV) at end-diastole (white arrow). AO, Aorta; LA, left atrium; LV, left ventricle.

even intracardiac disease.¹⁶ Relative to CT, MRI has the advantages of not requiring intravenous contrast injection and of having less motion artifact. MRI may be less sensitive than CT for detecting pericardial calcification. Newer MRI techniques can differentiate restrictive cardiomyopathy from constrictive pericarditis using speckle tracking to compare ventricular free wall strain relative to interventricular septal strain.¹⁰ Pericardial constriction is associated with smaller right ventricular volume and reduced mean trans-tricuspid E:A wave ratios.¹⁷

Cardiac Catheterization

Cardiac fluoroscopy can demonstrate pericardial calcification or abnormally prominent swinging motion of the left ventricle over the cardiac cycle in pericardial effusion. Right heart catheterization can be diagnostic of cardiac tamponade or pericardial constriction (see earlier; see Fig. 95-2). Both tamponade and constriction show equalization and elevation of diastolic pressures in all four chambers of the heart. Physiologic tamponade or constriction with right atrial mean pressure less than 14 mm Hg is unusual. Constriction may be differentiated from tamponade or restrictive cardiomyopathy by the square root sign in the right and left ventricular tracings (see Fig. 95-2), and the findings of cardiac constriction are accentuated by acute 500-mL volume challenge (see **Constrictive Pericarditis**, earlier). Given the noninvasive alternative imaging techniques available today, cardiac catheterization may be reserved for patients where clinical and noninvasive imaging data are inconclusive.¹⁸

Pericardiocentesis

Pericardiocentesis is a means to treat cardiac tamponade rapidly, to prevent tamponade in large effusions, and to obtain pericardial fluid for diagnosis. Contraindications include aortic dissection, coagulopathy, small or loculated

FIGURE 95-4 ■ Technique of subxiphoid pericardiocentesis with electrocardiographic monitoring. Note negative QRS deflection indicating myocardial contact. ECG, Electrocardiogram.

effusions, traumatic hemopericardium, and nonviral infectious pericarditis. Pericardiocentesis is generally performed with the patient supine and with local anesthesia. A long, pericardial needle is inserted into the patient's pericardial space left of the xiphoid, inferior to the left costal margin (Fig. 95-4). The needle is advanced toward the patient's left mid scapula while maintaining aspiration pressure on the needle. Cardiac puncture can be avoided by a combination of echocardiography and monitoring an ECG obtained by an electrode attached to the needle. The needle is withdrawn if the ECG shows sudden negative deflection of the QRS complex, indicating contact with the myocardium.

Once the pericardial space is entered, the needle can be exchanged over a wire for a blunt pericardial catheter. The blunt pericardial catheter can be left in the pericardial space for several days to decrease the rate of recurrent effusion (e.g., from 55% to 24%).¹⁹ Pericardial fluid can be sent to the laboratory for cell count and differential, cytology (possibly including tumor markers), culture (including bacterial, fungal, and mycobacterial), and biochemical examination (e.g., polymerase chain reaction for tuberculosis, pH, specific gravity, lactic dehydrogenase, protein content).³ Peripheral blood can be sent to the laboratory for leukocyte count and erythrocyte sedimentation rate, and for C-reactive protein, serum lactate dehydrogenase, and cardiac isoenzyme values.⁵

Pericardiocentesis is rapid and relatively safe, and it requires little anesthesia. Complication rates vary from 5% to 50% and are increased in smaller effusions, when echocardiographic guidance is not used, and in the presence of coagulopathy.¹⁹ Pericardiocentesis is less effective and less diagnostic in hemopericardium with clot, or in effusion with thick exudate. Most authors believe that pericardiocentesis is optimally used in patients with large anterior effusions and either with tamponade (therapeutic) or a probable infectious or tuberculous etiology (diagnostic).¹⁹ The rate of recurrent effusion and tamponade after successful pericardiocentesis is high (approximately 55%).¹⁹ The incidence of recurrent effusion or tamponade may be decreased by pericardial catheter drainage for 2 to 5 days or surgical drainage.

Pericardial Biopsy

Pericardial biopsy can be performed percutaneously with a pericardioscope or surgically (see [Pericardial Surgical Procedures](#), later).²⁰ Percutaneous pericardial biopsy is performed by dilating a pericardiocentesis needle track to accept an introducer sheath. A biptome can then be placed through the introducer using echocardiographic guidance to obtain pericardial biopsy.²¹ The value and safety of percutaneous pericardial biopsy have not been established.

Pericardial tissue can be examined to diagnose pericarditis, and together with pericardiocentesis it can demonstrate the cause of pericarditis in 30% to 50% of patients. Pericardial tissue may be sent for hematoxylin-eosin and Gram stains, polymerase chain reaction analysis for tuberculosis, and cultures for bacteria, fungus, and tuberculosis. Special stains can be used to detect certain forms of malignancy.

NONCONSTRICTIVE PERICARDITIS

Diagnosis

Using European Society of Cardiology guidelines, pericarditis has been classified as dry, effusive, effusive-constrictive, and constrictive.⁵ The diagnosis of pericarditis requires the pathologic demonstration of pericardial inflammation, scarring, or thickening. Thus certain diagnosis of pericarditis requires pericardial biopsy, generally with surgery to create a subxiphoid or transthoracic pericardial window. The diagnosis of pericarditis can, however, be strongly supported by findings of pericardial effusion or pericardial thickening on echocardiography, CT, or MRI. The diagnosis of pericardial effusion requires only an imaging study demonstrating more fluid than normal (>50 to 100 mL) in the pericardial space.

Etiology and Treatment

Pericardial effusion and pericarditis have a wide variety of causes ([Table 95-1](#)).^{5,22,23} Medical treatment for pericardial effusion should target the etiology of the effusion. Surgical treatment involves either pericardiocentesis or

TABLE 95-1 Frequency of Effusion and Constriction in Pericarditis

Etiology	Effusion (%)	Constriction (%)
Idiopathic	7-30	50-70
Viral	5-25	0
Bacterial	5-10	0-5
Tuberculous	5-10	15
Autoimmune	5-15	1
Type 2 immune or postoperative	5-25	5-60
Malignant	20-50	0
Traumatic or radiation	5-15	9-20
Metabolic or uremic	10-15	0
Surrounding structures	5	1

the creation of a subxiphoid pericardial window or a transpleural pericardial window. Pericardiocentesis or pericardial biopsy can be indicated to determine the cause of the pericarditis and thus define the medical therapy. In a hemodynamically unstable patient, pericardiocentesis is also indicated to treat pericardial tamponade acutely and to achieve hemodynamic stability. Pericardiocentesis can be as effective as pericardial window in achieving diagnosis and draining the pericardial effusion,²⁴ but pericardiocentesis is more likely than pericardial window to require recurrent treatment for recurrent pericardial symptoms.^{19,23,24}

Pericardial window is indicated in any patient with symptomatic pericardial effusion or in whom the cause cannot otherwise be defined. A subxiphoid pericardial window procedure can be performed using local anesthesia; therefore, it is preferable in patients in hemodynamically unstable condition because of tamponade but in whom pericardiocentesis is deemed impractical or unsafe. The transpleural pericardial window is preferable in patients with a good long-term prognosis because of a lower likelihood of recurrent pericardial effusion.²⁵ Pericardiectomy can improve relapse rate without significant increase in mortality for patients with chronic relapsing pericarditis.²⁶

Idiopathic Pericarditis

Idiopathic pericarditis is the diagnosis for 3% to 50% of all patients with pericardial effusion or pericarditis. Management is symptomatic, as it is for viral pericarditis. Symptoms of low-grade pain and fever can be treated with anti-inflammatory agents such as ibuprofen (300 to 800 mg every 6 to 8 hours for days to weeks) along with antiulcer agents. Colchicine 0.5 mg bid for 3 months in addition to ibuprofen or aspirin has been shown in a randomized trial to reduce symptoms, readmission, and hospitalization.^{22,27} More severe or refractory symptoms may respond to prednisone, beginning with 1 to 1.5 mg/kg per day and tapering over the 1- to 3-month course.⁵ Other causes such as infection or uremia need to be excluded before starting steroids. Intrapericardial steroids may be beneficial.³ Pericarditis can produce atrial fibrillation, which may also require treatment. Outcome from acute pericarditis is good, with the most common

complication being recurrent pericarditis.²⁷ Complete pericardiectomy can significantly improve freedom from relapse relative to medical therapy in patients failing medical therapy including steroids.²⁶

Infectious Pericarditis

At least 50% of infectious pericarditis is thought to be viral. The viruses associated with pericarditis include coxsackievirus, cytomegalovirus, echovirus, Epstein-Barr virus, varicella, parvovirus, human immunodeficiency virus, and herpes simplex.⁵ Viral pericarditis is a clinical diagnosis that is frequently made with the assistance of viral serologies. It is often accompanied by myocarditis, which can be documented on myocardial biopsy or indirectly suggested by acute deterioration of ventricular function. Like idiopathic pericarditis, it is usually self-limited. Pericardiocentesis or surgical pericardial drainage with biopsy is performed as needed for diagnosis or treatment of symptoms.

Nonviral infectious pericarditis is usually fatal if untreated, and it has a mortality of 8% to 40% in treated patients.⁵ The most common bacterial organisms causing pericarditis are *Staphylococcus*, *Streptococcus*, and gram-negative organisms in adults and *Haemophilus* or *Staphylococcus* in children. Bacterial pericarditis can occur from bacteremia or from contiguous spread from bacterial infection in the thoracic cavity. Symptoms of fever and chest pain are common. Diagnosis relies on culture or histologic examination of pericardial fluid obtained by either pericardiocentesis or open pericardial drainage.

Bacterial pericarditis requires both appropriate antibiotic treatment and either acute or chronic pericardial drainage. Bacterial pericarditis may respond to a one-time pericardial drainage, with systemic antibiotic therapy for less virulent organisms such as *Streptococcus*. Pericardiectomy may be necessary if initial drainage fails, especially in organisms such as *Haemophilus*.¹⁹ Constrictive pericarditis can develop at a rate of 5% per year after bacterial pericarditis.²² Fungal and staphylococcal pericarditis respond better to more chronic drainage of the pericardium by the subxiphoid or transthoracic approach.

Tuberculous pericarditis can appear with effusion or constriction, or both. Acute tuberculous pericarditis is best treated with intermittent pericardiocentesis. Tube drainage of tuberculous pericarditis is to be avoided to prevent chronic draining sinuses along the tube track. Pericardiectomy or open pericardial drainage (preferably after 1 week of chemotherapy) may be necessary if initial drainage fails, and pericardial constriction results in approximately half of patients with tuberculous pericarditis.²⁸ Amebic or echinococcal pericarditis can require pericardiocentesis or tube drainage depending on the thickness and degree of loculation.²⁹

Autoimmune Pericarditis

Connective tissue or inflammatory diseases such as rheumatoid arthritis, lupus, and systemic sclerosis can produce pericarditis in a minority of patients. The underlying condition should be treated if possible, and pericardiocentesis and pericardial window are reserved for

symptoms refractory to medical treatment or when needed to make a diagnosis.

Type 2 Immune and Postoperative Pericarditis

Type 2 immune pericarditis can occur 5 to 14 days after cardiac injury or operation. Only 10% of patients undergoing cardiac operation have clinically significant postoperative pericarditis, and symptoms are usually self-limited, resolving after 3 to 4 weeks. Intraoperative use of bioabsorbable films may diminish pericardial scarring without the pericardial capsule formation associated with nonabsorbable pericardial substitute material.³⁰ Treatment is similar to that given for idiopathic pericarditis.

Malignant Pericarditis

Malignant involvement of the pericardium is generally metastatic and occurs in approximately 10% to 35% of patients with noncardiac neoplasm. The most common tumors that involve the pericardium are lung (38%), breast (29%), and lymphoma (7%), with 26% being other tumors.³¹⁻³³ Primary malignancies of the pericardium are rare and include mesothelioma (50%), sarcoma, and malignant teratoma. Malignancy of the pericardium generally manifests as cardiac tamponade resulting from malignant pericardial effusion. Pericardial constriction resulting from malignancy is infrequent. Once pericardial effusion is demonstrated by an imaging study, the diagnosis of malignant pericardial effusion can be made by cytologic examination of pericardial effusion in 20% to 30% of cases. Pericardial biopsy doubles the diagnostic yield of pericardiocentesis alone. Pericardiocentesis has had some success, followed by sclerotherapy and also percutaneous balloon pericardiotomy.⁵ The longevity of patients with malignant pericarditis is sufficiently low that subxiphoid drainage and transthoracic drainage have similar success rates.³⁴ Median survival for malignant pericardial effusion requiring surgical intervention is less than 6 to 12 months.^{23,35} Rarely, good long-term results can be obtained with complete excision of localized primary tumors of the pericardium

Traumatic and Radiation-Induced Pericarditis

Only a small fraction of patients receiving mediastinal irradiation develop clinically significant pericarditis. Early pericarditis within 1 to 3 months of initiating mediastinal irradiation is generally self-limited and can be treated symptomatically, as idiopathic pericarditis is treated. Treatment with pericardiocentesis or pericardial window should be reserved for significant refractory symptoms or concern about other causes. A small number of patients may develop constrictive pericarditis, usually 5 to 20 years after irradiation.

Traumatic pericarditis along with hemopericardium and tamponade can result from cardiac intervention such as cardiac catheterization, coronary angioplasty, myocardial biopsy, and balloon valvuloplasty. Pericardiocentesis alone is usually effective if the puncture is isolated to the atria.⁵

Metabolic and Uremic Pericarditis

Metabolic causes of pericarditis include uremia, myxedema, Addison disease, diabetic ketoacidosis, and cholesterol pericarditis. Uremic pericarditis occurs in 20% of patients receiving hemodialysis and in 50% of patients with severe untreated renal disease. Patients may have chronic pericardial thickening that classically looks “shaggy.” Other dialysis patients have less pericardial thickening and significant pericardial effusions because of chronic volume overload.⁵ Therapy for uremic pericarditis is focused on treating tamponade. Intensive hemodialysis may avert tamponade in patients with uremic pericarditis, but pericardial tamponade is most effectively treated by pericardial drainage. Tamponade may respond to pericardiocentesis initially, but the incidence of recurrent tamponade in uremic pericardial effusion is highest with pericardiocentesis alone, better with subxiphoid pericardial window, and lowest with transthoracic pericardial window.¹⁹

Pericarditis from Surrounding Structures

Pericarditis can develop after acute myocardial infarction (Dressler syndrome), aortic dissection, pneumonia, pulmonary infarction, and esophageal disease. Other causes must be excluded. Treatment is focused on the underlying pathology, with care needed to prevent tamponade resulting from myocardial or aortic rupture in patients with larger effusions.⁵

Chylopericardium

Chylopericardium can be idiopathic or follow thoracic surgery. It can be treated with pericardiocentesis or, if recurrent, with subxiphoid or transthoracic pericardial window with or without low thoracic duct ligation.³

Hemopericardium

Hemopericardium can result from trauma, recent mediastinal operation, coagulopathy, cardiac perforation owing to instrumentation, cardiac rupture, or aortic rupture. Acute hemopericardium resulting in cardiac tamponade requires emergent treatment (see [Cardiac Tamponade](#), later). In the absence of cardiac tamponade, the treatment of hemopericardium depends on the underlying disease process. Hemopericardium caused by percutaneous cardiac (especially atrial) puncture in the catheterization laboratory can generally be remedied by placing a pigtail catheter in the pericardial space, reversing anticoagulation, aspirating frequently with the pigtail catheter, and watching for cessation of bleeding.

Hemopericardium caused by surgical diseases such as acute aortic dissection, cardiac or aortic rupture, or penetrating trauma is best treated by tube drainage of the pericardium after surgically correcting the source of the bleeding. Hemopericardium caused by blunt trauma or coagulopathy may require surgical drainage by either the subxiphoid or the transthoracic approach to prevent acute tamponade and late pericardial constriction.

Pneumopericardium

Pneumopericardium is a rare condition that most commonly results from severe chest trauma with associated lung injury, or from spontaneous dissection of air from a ruptured bleb in neonates on positive-pressure ventilation.³⁶ Symptoms are unusual, although tamponade occurs in 37% of patients. Treatment focuses on the underlying disease. Pericardiocentesis or pericardial tube drainage can be effective in patients with tamponade. Mortality is high (58%) because of underlying disease.

CARDIAC TAMPONADE

Etiology

A common cause of acute pericardial tamponade is hemopericardium after recent mediastinal surgery or percutaneous cardiac instrumentation. Other causes include pneumopericardium and hemopericardium resulting from coagulopathy. Approximately half of patients with chronic pericardial effusion present with cardiac tamponade. Malignant effusion and uremic pericarditis are common causes of chronic cardiac tamponade (see [Table 95-1](#)).

Diagnosis

Physical examination may show pulsus paradoxus and jugular venous distention. Cardiac tamponade can be diagnosed using right heart catheterization or echocardiography (see [Table 95-1](#)). For right heart catheterization, cardiac output is typically reduced with elevation of central venous pressure of at least 14 mm Hg, and with equalization of the central venous pressure, pulmonary artery diastolic pressure, and capillary wedge pressure. Echocardiography will show the pericardial space distended with fluid, with right atrial compression or diastolic right ventricular collapse (or both), and inspiratory interventricular septal shift leftward with increased tricuspid and pulmonic flow velocities and decreased mitral and aortic flow velocities (see [Fig. 95-3](#)).¹³ Although 80% of patients have pericardial effusions on echocardiography in the first 3 weeks after heart surgery, a moderate or large pericardial effusion has been associated with a 75% likelihood of developing tamponade.³⁷

Treatment

Cardiac tamponade resulting from hemopericardium within several days after a surgical procedure is almost always managed by returning to the operating room once coagulopathy is corrected. Back in the operating room, the hemopericardium should be evacuated (generally through the original surgical incision) and drains should be left in the pericardial space.

In the absence of a recent cardiac surgical procedure, patients with cardiac tamponade and hemodynamic compromise can usually be stabilized with emergent pericardiocentesis. Depending on the cause of the tamponade, a single pericardiocentesis may be all that is needed.

Otherwise, a pigtail catheter may be left in the pericardium for up to 48 hours, or more definitive pericardial drainage by the subxiphoid or transpleural window may be desirable.

Subxiphoid pericardial window is ideal for many patients with tamponade, because local anesthesia can be used to avoid the hemodynamic embarrassment of general anesthesia in an unstable patient. Transpleural approaches are less suitable for the unstable patient because of intolerance of one-lung anesthesia or pleural insufflation of carbon dioxide. In patients for whom transpleural pericardial window has advantages, an initial pericardiocentesis should be done to relieve tamponade before anesthetic induction for transpleural drainage. Paradoxical hemodynamic instability after relieving pericardial tamponade is associated with poor long-term survival and may be due to underlying ventricular dysfunction.³¹

CONSTRICTIVE PERICARDITIS

Etiology

The most common etiology of constrictive pericarditis in Western countries is idiopathic, with prior cardiac operation and mediastinal irradiation also being common (see [Table 95-1](#)).³⁸⁻⁴⁰ As in earlier decades in the West, tuberculosis in developing countries today is the leading cause of constrictive pericarditis.⁴¹ Pericardial closure at the time of routine cardiac operation can induce some degree of immediate pericardial constriction and decreased cardiac index,⁴² and it probably increases the small but real incidence of late constrictive pericarditis. Although routine pericardial closure at the time of cardiac operation can decrease the risk of sternal reentry, some authors have recommended avoiding pericardial closure in patients with ventricular dysfunction, risk of tamponade, or older age when there is a low likelihood of reoperation.⁴²

Diagnosis

Physical examination may show jugular venous distention and Kussmaul sign. Pericardial thickening with minimal pericardial fluid on echocardiography, CT, or MRI is present in 85% of patients.¹²⁻¹⁴ Pericardial thickening supports the diagnosis, but the pericardium might not be thickened in 15% to 18% of patients with constriction (see [Fig. 95-2](#)). Diagnosis of constrictive pericarditis requires demonstration of the right heart hemodynamics typical of constriction (see [Fig. 95-2](#)). The findings at right heart catheterization include decreased cardiac output, equalization of diastolic right-sided pressures, and the characteristic square root sign with a steep γ descent in right and left ventricular diastolic pressure tracings (see [Box 95-2](#) and [Fig. 95-2](#)). Detection of these findings can be augmented with a 500-mL volume challenge at the time of right heart catheterization.

Treatment

The treatment for pericardial constriction is pericardiectomy (see [Pericardiectomy](#), later). Patients should be

referred before onset of class IV symptoms to minimize postoperative mortality and low cardiac output.³⁸ Approximately 20% of patients with constriction have at least moderate tricuspid regurgitation, which in turn is associated with worse 5-year survival (47% vs. 87%). Significant tricuspid regurgitation in patients undergoing pericardiectomy should prompt consideration of tricuspid operation.⁴³ Rarely, the underlying cause also requires treatment, such as for tuberculous pericarditis.⁴¹ Perioperative mortality can be significantly increased with a Class B or C Child-Pugh score.⁴⁴ Long-term survival in selected patients without myocardial involvement can approach that of the general population.^{39,40,45}

PERICARDIAL CYSTS AND DIVERTICULA

Pericardial cysts and diverticula are usually congenital and occasionally inflammatory in origin, and they represent 10% to 20% of all mediastinal masses.^{46,47} Pericardial cysts and diverticula have a fibrous wall lined with mesothelium, whereas bronchial cysts have bronchial epithelium. Pericardial cysts occur more often in men than in women. Most pericardial cysts and diverticula appear as asymptomatic masses on chest radiography, and one third of patients present with chest pain. Pericardial cysts are found at the right costophrenic angle in 77%, at the left costophrenic angle in 22%, and in other areas (posterior mediastinum, hilar region, right paratracheal region, or aortic arch) in 8%.⁴⁶⁻⁴⁸ Pericardial diverticula communicate with the pericardium and comprise 20% of combined pericardial cysts and diverticula.⁴⁸ Cysts or diverticula found to have low fluid density on CT or MRI need no further workup. Masses with a density higher than that of transudate may need further workup to exclude other pericardial masses ([Fig. 95-5](#)). Cysts or diverticula that need to be removed to exclude malignancy can be approached thoroscopically or via thoracotomy. Even when malignancy is unlikely, some authors have recommended excision of most pericardial cysts to prevent complications of rupture, cardiac compression, or tracheal compression.^{47,48} Percutaneous cyst aspiration and chemical sclerosis may also be feasible and are preferable to surgery for echinococcal cysts.⁵

PERICARDIAL TUMORS

Most pericardial tumors appear with malignant pericardial effusions resulting from malignant metastases from lung, breast, or lymphoma (see [Malignant Pericarditis](#), earlier). Primary pericardial tumors include lipoma, hemangioma, lymphangioma, leiomyoma, neurofibroma, heterotopic thymus or thyroid, teratoma, mesothelioma, thymoma, liposarcoma, angiosarcoma, and synovial sarcoma. Half of all primary pericardial malignancies are mesotheliomas, with angiosarcoma being the next most common primary malignancy. The differential diagnosis includes pericardial cysts and pericardial diverticula (see earlier), which can often be distinguished with CT or MRI.³³

FIGURE 95-5 ■ **A**, Chest radiograph of a patient with a large left-sided pericardial cyst. **B**, Computed tomographic scan of the same patient showing the pericardial cyst extending into the left hemithorax.

Once identified, primary pericardial tumors should be removed if possible. Depending on location and size, either median sternotomy, thoracotomy, or thoracoscopy can be used to approach primary pericardial tumors. Prognosis depends on tumor type and extent. Lipomas, leiomyomas, and heterotopic tissue are generally resectable and have an excellent prognosis. Mesotheliomas almost always spread to contiguous structures in the pericardium, adjacent pleura, and occasionally mediastinal lymph nodes. Mesotheliomas are rarely resectable, and no treatment has been shown to be effective. Survival with pericardial mesothelioma may be 40% at 6 months.⁴⁶

PERICARDIAL DEFECTS

Congenital defects of the pericardium are rare, occurring in 1 in 10,000 autopsies, with a 5:1 male-to-female predominance.⁴⁷ Approximately 30% of patients with pericardial defects have associated cardiac or pulmonary anomalies. The mean age at diagnosis is 20 years. Complete absence of the pericardium is rare but generally asymptomatic.

Partial pericardial defects are left sided in 70% of cases, and they can produce symptoms by compressing the left atrial appendage, allowing cardiac herniation, or even compressing coronary arteries.⁴⁹ Partial pericardial defect can have some risk of death from cardiac herniation, coronary compression, or traumatic aortic dissection.⁵ One third of patients are asymptomatic and are detected by abnormal chest radiograph. Symptoms of partial pericardial defect include sharp, fleeting chest pain that is often positional.⁵⁰ Other symptoms include dyspnea, sweating, syncope, and circulatory collapse.

When there is complete or partial absence of the pericardium, the chest radiograph is always abnormal, with

rotation and leftward displacement of the heart placing the right heart border over the spine. CT and MRI can similarly show displacement and rotation of the heart into the left chest. The presence of a tongue of lung between the pulmonary artery and the aorta is pathognomonic for congenital absence of pericardium.⁵⁰

Complete pericardial absence requires no treatment.⁵⁰ Partial left pericardial defects not overlying the left ventricle may be observed if asymptomatic. Patients with symptoms or partial pericardial defects overlying the left ventricle should be treated surgically to prevent cardiac herniation or compression. Surgical approaches include either sternotomy or thoracoscopy to perform pericardiectomy, repair the pericardial defect with a patch, or amputate the left atrial appendage.⁴⁹

Pericardial rupture can occur as the result of blunt trauma, and it is associated with cardiac injury, cardiac rupture, and cardiac tamponade.⁵¹ Pericardial rupture should be repaired to prevent cardiac herniation, but only after associated cardiac injuries are repaired. Mortality is greater than 50%.⁵

PERICARDIAL SURGICAL PROCEDURES

Subxiphoid Pericardial Window

For patients requiring more extensive pericardial drainage than is possible through pericardiocentesis, the subxiphoid pericardial window is an excellent option that minimizes morbidity, especially in patients who are hemodynamically compromised by cardiac tamponade. The subxiphoid pericardial window provides excellent drainage of the pericardial space, allows placement of large-bore pericardial tubes, and potentially drains the right pleural space. An additional advantage is that the

FIGURE 95-6 ■ Technique of subxiphoid pericardial window. **A**, A 7-cm subxiphoid incision is made, the linea alba is opened, and the xiphoid process is excised. **B**, A 2 × 2-cm opening is made in the pericardium, and a tube drain is placed in the pericardial space. (From Glover DD: Pericardial window. In Sabiston DC Jr, editor: *Atlas of cardiothoracic surgery*, Philadelphia, 1995, WB Saunders.)

subxiphoid pericardial window can be created with either local or general anesthesia. Local anesthesia is preferable for patients who are hemodynamically compromised by pericardial tamponade.

After either anesthesia is established, a 6- to 12-cm incision is made in the midline from the cephalad end of the xiphoid to 1 to 2 cm inferior to the xiphoid (Fig. 95-6). The linea alba is divided at the midline, and the xiphoid process is either removed or retracted. With sharp and blunt dissection continuing superiorly and to the patient's left, the pericardium is identified using upward retraction on the sternum and costal cartilages as necessary. Identification of the pericardium can be confirmed by needle aspiration of the pericardium to obtain fluid before making the incision into the pericardial space. When the pericardium is identified, a 4-cm-diameter piece of anterior pericardium is excised. The pericardium and pericardial fluid may be sent for histology and culture. Optionally, the pericardial window can be opened into the right pleural space to drain any right pleural effusion. An angled chest tube can then be placed on the diaphragm in the pericardial space, and an additional chest tube could be placed in the right pleural space. Chest tubes should be brought through the rectus muscle lateral to the incision. The linea alba and remaining incision are then closed.

The mortality directly related to subxiphoid pericardial window is 1% or less, and survival is limited by the underlying disease (50% to 60% survival at 1 year).^{23,24,31} The effectiveness in treating tamponade is nearly 100%, and the diagnostic yield is 40% to 80%.^{24,31} Recurrent effusion or constriction can occur in 9% to 25% of patients,²³ and it may be more likely after transthoracic pericardial resection for patients with benign disease.²³

Pericardioscopy

Pericardioscopy has been performed with general anesthesia using the same technique as subxiphoid pericardial window described earlier. Once the pericardial window has been created, a flexible scope is introduced into the pericardial space.²⁰ The pericardial space is inspected for gross diagnostic purposes, and endoscopically guided biopsy specimens can be obtained. Pericardioscopy combined with pericardiocentesis and subxiphoid pericardial window has been reported to provide a specific diagnosis in 64% of cases, significantly greater than with pericardiocentesis or pericardial window alone.

Transpleural Pericardial Window

A left thoracotomy is generally used to treat hemodynamically stable patients with pericardial effusion and with good long-term prognosis. Thoracotomy may be desired if simultaneous lung biopsy is needed, and chronic pericardial drainage may be more effective than subxiphoid approaches in nonmalignant pericarditis. Thoracotomy is relatively contraindicated in patients with purulent pericarditis to avoid contamination of the pleural space.

A left thoracotomy (as opposed to right thoracotomy) is generally preferred for open transpleural pericardial window because more pericardium is accessible from the left. The patient is placed supine with the left side elevated 30 degrees. General anesthesia is standard, and left lung isolation is optional with either a dual-lumen endotracheal tube or an endobronchial blocker. A 5- to 12-cm submammary incision is made, and the fifth or fourth intercostal space is entered. The lung is retracted

laterally, and the internal mammary artery can generally be spared medially. The left anterior pericardium is opened anterior to the phrenic nerve, taking care not to injure underlying heart and maintaining hemostasis on the pericardial edge with gentle electrocautery. Pericardium can be excised from 1 to 2 cm anterior to the phrenic nerve to the midsternal level. Pericardium posterior to the phrenic nerve can also be excised, although the indications for posterior pericardial resection are unclear. Because left thoracotomy is generally used in patients with good long-term prognosis, studies suggest that at least a 4 × 4-cm piece of pericardium should be excised to prevent recurrent pericardial effusion resulting from adhesions.^{23,25} A pleural drain is left in place, and the thoracotomy is closed in a standard fashion.

Transpleural pericardial window can also be performed using direct or video-assisted thoracoscopy in patients with pericardial effusion without hemodynamic compromise resulting from tamponade. Either the right or the left approach can be used, depending on where the greater pericardial pathology lies, but left thoracoscopy may allow only limited operating space because of the proximity of the distended pericardium to the chest wall. The patient is positioned in a lateral decubitus position (Fig. 95-7). The trocar for the video thoracoscope is initially placed posteriorly, being careful to avoid pericardium, which might extend laterally. Two additional triangulated trocars are then placed for instrumentation. The pericardial window procedure is then performed as in the open transpleural approach just described. An ultrasonic scalpel has been useful for achieving hemostasis on the pericardial edges without the risk of ventricular arrhythmia caused by electrocautery.⁵²

The mortality directly related to transthoracic pericardial window is 1% or less, although operative mortality can be 19% for patients with malignant disease and 5% for those with benign disease.²³ The effectiveness in treating tamponade is nearly 100%, and the diagnostic yield is 40% to 80%.^{19,23} Recurrent effusion or

constriction occurs in 5% of patients, as opposed to 25% with the subxiphoid pericardial window.²³

Transdiaphragmatic Pericardial Window

Transdiaphragmatic pericardial window can be performed using standard laparoscopic techniques or by resecting part of the diaphragm at the time of subxiphoid pericardial window. For the endoscopic approach, a camera is inserted supra-umbilically with trocars in the right and left hypochondria. A 3- to 5-cm-diameter opening in the diaphragm and pericardium is made to drain the pericardium into the peritoneal cavity.⁵³ As with thoracoscopic pericardial window, the ultrasonic scalpel has advantages over electrocautery for minimizing ventricular arrhythmias, smoke, and stimulation of the diaphragm.

Pericardiectomy

Pericardiectomy is usually done through a median sternotomy because of the likelihood of pericardial adhesions that may be dense and because of the bilateral extent of the pericardium. Pericardiectomy is possible through bilateral thoracotomies, and left anterolateral thoracotomy (fifth interspace) has been used to achieve effective pericardiectomy.^{38,43,45}

For sternotomy, a midline incision is made from just inferior to the suprasternal notch to the inferior extent of the xiphoid process (Fig. 95-8). The entire extent of the sternum is divided in the midline with a sternal saw, and the sternum is opened with a sternal retractor. A relatively thin area of anterior pericardium is incised, and a plane between the epicardium and the pericardium is established using sharp dissection. If possible, the pericardium is opened in the midline from the level of the diaphragm to the base of the great vessels. Tradition states that the left ventricle should be freed first to avoid

FIGURE 95-7 ■ **A**, Thoracoscopic pericardial window with patient in the right lateral decubitus position. The three trocar sites are shown with the camera placed in the posterior port. **B**, Thoracoscopic view of the pericardial resection. (From Inderbitzi R, Furrer M, Leupi F: Pericardial biopsy and fenestration. *Eur Heart J* 14:135–137, 1993.)

FIGURE 95-8 ■ Technique of pericardiectomy. Median sternotomy is performed, and the pleural spaces are opened bilaterally. The anterior pericardium is excised from the diaphragm inferiorly to the great vessels superiorly and 1 to 2 cm anterior to the phrenic nerves bilaterally. As indicated, the diaphragmatic pericardium and the pericardium posterior to the phrenic nerves can also be excised. Unresectable, thickened epicardium may be scored. (From Glower DD: Pericardiectomy for constrictive pericarditis. In Sabiston DC Jr, editor: *Atlas of cardiothoracic surgery*, Philadelphia, 1995, WB Saunders.)

right ventricular distention, although the frequency of this problem is unclear. The anterior pericardium is freed from 1 to 2 cm anterior to the right phrenic nerve to 1 to 2 cm anterior to the left phrenic nerve laterally, and from the base of the great vessels superiorly on to the diaphragm inferiorly. Occasionally, dense epicardial scar may be impossible to remove without risk of cardiac injury. In that case, the remaining epicardial scar can be carefully incised in a grid pattern of crossing lines 1 to 2 cm apart (waffle procedure), although the effectiveness of this technique is unclear.⁵⁴ Once freed from the epicardium, the pericardium can be excised using low electrocautery to achieve hemostasis. Care should be taken to avoid injury to the phrenic nerves, which may be difficult to identify.

Anterior pericardiectomy (described earlier) can usually be performed without cardiopulmonary bypass, and it provides the majority of the hemodynamic benefit to be obtained in relieving constriction of the right ventricle. Resecting the atrial pericardium may be less important than resecting the ventricular pericardium, making pericardiectomy via left thoracotomy practical in many cases.⁴⁴ However, some authors have advocated excising pericardium posterior to the phrenic nerves on the left or bilaterally to decrease atrial constriction and prevent recurrent constriction.^{38,41,55} Posterior pericardiectomy frequently requires cardiopulmonary bypass because of the cardiac manipulation necessary,³⁸ but with little increase in morbidity.⁴³ Pericardiectomy for constriction provides excellent symptomatic improvement, with 85% of late survivors being New York Heart Association (NYHA) class I and the remainder being class II.³⁸ Operative mortality for pericardiectomy for constriction is 6% to 14%,^{39,56,57} primarily because of persistent low

cardiac output (seen in 70% of deaths).^{38,58} Operative mortality is increased by preoperative NYHA class, (being 1% for classes I and II, 10% for class III, and 46% for class IV).³⁸ Child-Pugh score, mediastinal irradiation, age, renal disease, and lack of calcification (Fig. 95-9).^{40,44,57} Normalization of hemodynamics is achieved in 60% of patients,⁷ and normalization of hemodynamics is associated with improved short- and long-term survival.⁴⁵

SURVIVAL

COMPARISON TO SEPTAL ARTERY ABLATION

SPECIAL SUBGROUPS

DEFINITION

Hypertrophic cardiomyopathy (HCM), the most common genetic cardiac disease, occurs in approximately 1 in 500 young adults.^{1,2} It is defined as left ventricular (LV) hypertrophy in the absence of an underlying cause, such as systemic hypertension or valvular aortic stenosis.³ In the obstructive form of HCM, septal hypertrophy and abnormal systolic anterior motion of the mitral valve combine to produce left ventricular outflow tract (LVOT) obstruction and variable degrees of mitral valve regurgitation; outflow tract obstruction in HCM is distinct in morphologic appearance and prognosis from congenital membranous subaortic stenosis.⁴ In addition, some patients will have symptoms because of midventricular

obstruction.^{5,6} The condition is important for surgeons because obstruction may occur in more than 70% of patients with HCM,⁷ and transaortic septal myectomy is highly effective in the management of hypertrophic obstructive cardiomyopathy.

HISTORICAL NOTE

The modern description of HCM is credited to Robert Donald Teare, a London pathologist, who in 1958 likened the pathologic findings to “a tumor of the heart” and recognized asymmetrical hypertrophy and myocyte disarray as a familial condition associated with premature and sudden death in young people.⁸ In a subsequent paper in 1960, Teare proposed the term *obstructive*

cardiomyopathy.⁹ In 1957, Brock¹⁰ described a 58-year-old woman with breathlessness, angina, and syncope who was referred with the diagnosis of aortic valve stenosis. At operation, the valve was normal, and subaortic muscular obstruction was found. Despite attempts to relieve this with dilators, the patient had a residual gradient above 90 mm Hg and died postoperatively. An autopsy confirmed muscular subvalvar stenosis 2.5 cm below the aortic valve, but the histology was never defined.

At the same time, Bercu and colleagues¹¹ described the familial occurrence of unexplained ventricular hypertrophy simulating aortic stenosis as “pseudo-aortic stenosis.” Working at the National Institutes of Health, Morrow and Braunwald reported “functional aortic stenosis” and made fundamental contributions to the understanding of clinical and pathophysiologic features of the HCM.¹² The genetic nature of the disease was suggested by Brent and colleagues, who reported two families with “familial muscular subaortic stenosis” compatible with transmission by a mendelian dominant gene.¹³

Hypertrophic obstructive cardiomyopathy (HOCM) was the term applied to the condition by Goodwin,¹⁴ Holman, and others; Braunwald and associates¹⁵ popularized the term *idiopathic hypertrophic subaortic stenosis*. Asymmetrical septal hypertrophy previously was considered to be specific for the disease,^{16,17} but it is now recognized that asymmetrical septal hypertrophy is simply a variant of HCM in which there is a predominance of septal hypertrophy. In current practice, the broad definition, HCM, is generally accepted, recognizing that not all patients have the same distribution of hypertrophy and that LVOT obstruction is not present in all phases of the disease or in all patients.

Surgeons were aware of HCM after Brock's reports and the publication by Kirklin from the Mayo Clinic in 1958.^{10,18,19} Effective treatment of outflow tract obstruction began with a simple myotomy, an incision in the hypertrophied septum as described by Cleveland and others.²⁰⁻²² Subsequently, septal myectomy was used to relieve outflow tract obstruction, and this approach has been favored at our clinic since the earliest reports by Kirklin.¹⁹ Barratt-Boyes and associates advocated excision of the hypertrophied septum through a combined approach with incision in the left ventricle and the aorta.²³ Other approaches to septal myectomy include the left atrial approach with exposure of the hypertrophied septum after division of the anterior leaflet of the mitral valve²⁴; Lillehei used a similar method but detached the base of the mitral leaflet to expose the septum.²⁵ Swan described the use of a corkscrew to excise septal muscle from a limited LV approach,²⁶ and Julian used a curvilinear LV incision that detached the lower part of the free wall of the septum to expose the septal bulge.²⁷

Thickness of the hypertrophied septum can be reduced by shaving the right ventricular side through right ventriculotomy,^{28,29} but this technique is less direct than the transaortic approach. Because systolic anterior motion of the mitral valve is an integral part of the mechanism of LVOT obstruction, excision of the mitral valve and replacement with a low-profile prosthesis, as described by Cooley and coworkers, is an effective method of

relieving outflow tract obstruction.³⁰ This, however, leaves the patient with potential hazards of a prosthetic valve. Rarely, an apicoaortic conduit has been used to relieve complex forms of LVOT obstruction caused by HCM.³¹

All of these earlier methods have been largely replaced by the more predictable and complete transaortic myectomy advocated by Morrow,³² and this is the basis of the extended septal myectomy, the surgical approach we favor that is described here.

CLASSIFICATION

Morphology

Distribution of Hypertrophy

Figure 96-1 shows the variable distribution of LV hypertrophy in patients with HCM. Classically, the anterior basal septum is thickest just cephalad to the anterior leaflet of the mitral valve in its open position. This subaortic obstruction may be accompanied by diffuse ventricular hypertrophy (see Fig. 96-1E), or the hypertrophy may be limited to the septum (asymmetrical septal hypertrophy; see Fig. 96-1B). There may be obstruction in the mid ventricle where hypertrophy of septum leads to contact with the papillary muscles producing obstruction to ejection of blood; in other patients, there may be an apical distribution of hypertrophy (see Fig. 96-1F). The phenotype of the disease and the appearance and severity of hypertrophy do not correlate with genotype; multiple ventricular morphologic appearances may be found in the same family.

Mitral Valve

In the classic form of HOCM, the mitral valve, especially the anterior leaflet of the valve, moves anteriorly during systole. The posterior leaflet closes against the mid- and free-edge third of the anterior leaflet instead of at the free edge as occurs normally. The free edge of the anterior leaflet is then displaced upward and narrows the LVOT. In addition, the anterior displacement of the valve leaflets produces mitral regurgitation of variable degree, which is typically directed posterolaterally.³³ A recent cardiac magnetic resonance imaging study suggested that the length of both the anterior and posterior leaflets of the mitral valve are increased in HCM patients compared to control patients, and the ratio of anterior mitral leaflet length to LVOT diameter of greater than 2.0 was associated with subaortic obstruction.³⁴

Mitral regurgitation is an important pathophysiologic component of HOCM and contributes to the symptoms of dyspnea and fatigability. Apposition of the anterior leaflet to the bulging septum produces a contact lesion, the whitish endocardial scar, which is useful in guiding septal myectomy. The occurrence of systolic anterior motion is often dynamic, and provocative maneuvers such as Valsalva, squatting, exercise, and, in some cases, adrenergic stimulation may be necessary to elicit systolic anterior motion, mitral regurgitation, and LVOT obstruction. The mechanism of systolic anterior motion

FIGURE 96-1 ■ Morphologic subtypes of hypertrophic cardiomyopathy. Hypertrophy may be localized to the basal septum, as in **B**; diffuse, as in **E**; or predominantly apical, as in **F**. Normal ventricular morphology is shown in **A**. (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

is debatable, and proposed mechanisms include the Venturi (pull) effect^{35,36} and a drag (push) effect.^{37,38}

Anomalies of papillary muscles are present in 15% to 20% of patients with HCM who undergo myectomy.³⁹ These abnormalities include anomalous papillary muscles, direct insertion of papillary muscles into the anterior mitral valve leaflet (Fig. 96-2), fusion of the papillary muscle to the ventricular septum or LV free wall, and accessory muscles and accessory anomalous chordae (false cords). In most cases, these abnormalities do not complicate myectomy or contribute to outflow tract obstruction; however, in some patients, anomalous papillary muscles, especially those that insert directly into the anterior leaflet, can contribute to outflow tract obstruction.⁴⁰

Right Ventricle

Right ventricular wall thickening has been documented in approximately one third of patients with HCM, and 10% have extreme right ventricular wall hypertrophy (≥ 10 mm).⁴¹ Right ventricular hypertrophy, however, rarely leads to fibrosis as evidenced by hyperenhancement on magnetic resonance imaging, and right ventricular outflow tract obstruction caused by infundibular narrowing is uncommon^{42,43} and mainly limited to cases of HCM manifested in children and young adults.⁴⁴ Right ventricular hypertrophy also occurs as a result of pulmonary hypertension from elevated LV end-diastolic pressure. Indeed, among patients referred for septal myectomy, pulmonary hypertension (right ventricular systolic pressure ≥ 35 mm Hg) was present in approximately half of the patients and severe pulmonary hypertension (right ventricular systolic pressure ≥ 50 mm Hg) was seen in 17% of patients.⁴⁵

FIGURE 96-2 ■ Anomalous papillary muscles may insert directly into the anterior mitral leaflet and contribute to outflow obstruction. When the anomalous muscle does not support the free edge of the valve, it can be excised. (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

Aortic Valve

In contrast to congenital membranous subaortic stenosis,⁴⁶ LVOT obstruction in patients with HCM does not directly affect the aortic valve. Aortic valve regurgitation has been observed after transaortic myectomy as a result of iatrogenic injury.⁴⁷

Coronary Arteries

Coronary arteries are larger than normal in patients with HCM, and basal coronary flow is increased in the resting state. Coronary flow reserve, however, is decreased in symptomatic patients with HCM compared with controls, and phasic flow is abnormal with a greater amount of flow during diastole, the presence of flow reversal in systole, and a more rapid deceleration of diastolic blood flow compared with normal patients. Decreased flow reserve is associated with a reduction in coronary resistance, suggesting that the mechanism is not a result of narrowing of intramyocardial small arteries or compression of the microcirculation; indeed, the reduction in coronary flow reserve in patients with HCM may be the result of almost maximal vasodilation of the microcirculation in the basal state. It has been speculated that compression of the microcirculation during systole may be the cause of flow reversal in patients with HCM and the inverse correlation between systolic flow and septal thickness; total coronary blood flow in patients with HCM, however, is preserved and even increased under resting conditions.

Atherosclerotic coronary artery disease is present in approximately 5% to 15% of patients with HCM, depending on the population studied. At the Mayo Clinic, significant coronary artery disease was detected in half of patients who were selected for coronary angiography, and disease was severe in 26%.⁴⁸ Survival of HCM patients with obstructive coronary artery disease is reduced compared with that of HCM patients without coronary artery disease, and survival is also poorer than that of patients without HCM who have comparable coronary artery disease and normal ventricular function.

Muscle bridging of the left anterior descending coronary artery (LAD) is not uncommon, occurring in 15% of patients with HCM undergoing coronary angiography at our clinic.⁴⁹ It is unclear whether bridging of the LAD plays a pathophysiologic role in the disease and associated symptoms of angina. However, for adult patients, risk of death and, in particular, of sudden cardiac death is not increased among patients with HCM with myocardial bridging. In contrast, Yetman and coworkers⁵⁰ reported that among children with HCM, systolic compression of LAD was present in 285 cases and was associated with a greater incidence of chest pain (60% vs. 19%; $P = 0.04$), cardiac arrest with subsequent resuscitation (50% vs. 4%; $P = 0.004$), and ventricular tachycardia (80% vs. 8%; $P < 0.001$). Myocardial ischemia was postulated to be the cause of this poor outcome.

Histopathology

Myocardial Fiber Disarray

A characteristic histologic feature of HCM is myocardial fiber disarray, which consists of short runs of severely hypertrophied fibers interspersed by connective tissue. Myocytes show large, bizarre nuclei with degenerating muscle fibers and fibrosis. It is the disorganized whirling of muscle fibers that is characteristic of HCM. Myocardial disarray is present in the ventricular septum and in

the LV free wall, but it is not pathognomonic for HCM. Fiber disarray may be present in myocardium in any conditions in which there is pressure overload, but the proportion of myocardial disarray is much greater in HCM.^{51,52}

Myocyte disarray has been associated with systolic dysfunction, ventricular dilation, and congestive heart failure.⁵³ It may also be a substrate for ventricular arrhythmias. Disarray has also been greatest in hearts with only a mild degree of LV hypertrophy or with absence of a subaortic mitral valve contact lesion, but there seems to be no direct relationship between myocyte disarray and fibrosis or small vessel disease.⁵⁴

Interstitial Fibrosis

Interstitial fibrosis is an important histologic feature that is present in variable degrees in the ventricle of patients with HCM.^{55,56} It is important not only as a mechanism of diastolic dysfunction but also because fibrosis detected by magnetic resonance imaging has been associated with arrhythmogenesis and risk of sudden cardiac death.^{57,58}

Differential Diagnosis

Other diseases may mimic HCM. Cardiac amyloidosis is an infiltrative disorder of the myocardium that typically produces diastolic dysfunction. Up to 30% of patients with cardiac amyloidosis have prominent subaortic thickening that produces LVOT obstruction. The clinical features and hemodynamics of patients with cardiac amyloidosis are similar to those of patients with LVOT obstruction caused by HCM. The finding of LV granular speckling on echocardiography should raise the suspicion of cardiac amyloid, especially if atrial wall thickness is increased.⁵⁹ Newer techniques of strain and strain rate imaging from speckle tracking may improve discrimination of cardiac amyloidosis from HCM.⁶⁰

Amyloid deposits may be identified incidentally in myectomy specimens of patients with typical features of obstructive HCM, and the mid-term postoperative survival of such patients is similar to that of an age- and sex-matched HCM population without amyloidosis undergoing septal myectomy. In these patients the most common subtype is senile amyloid, which has a good prognosis and rarely leads to multisystem involvement.

Patients with Fabry's disease may present with ventricular hypertrophy and dynamic LVOT obstruction. The mechanism of cardiac hypertrophy is different from that in other infiltrative cardiomyopathies in that it is secondary to increased cardiac muscle mass and infiltration of glycosphingolipids. The disorder caused by α -galactosidase A deficiency can be treated by enzyme replacement therapy, but ventricular hypertrophy and LVOT obstruction may persist and septal myectomy can relieve cardiac-related symptoms.⁵

GENETICS

HCM has a prevalence of 0.2% for phenotypically expressed disease.⁶¹ Approximately 60% to 80% of cases

are familial, and the remainder result from de novo mutations.⁶² HCM is genetically diverse, involving sarcomeric and nonsarcomeric proteins, and hundreds of mutations in more than 15 genes have been identified; indeed, double and compound heterozygosity and homozygosity have been reported.⁶³

Most patients with familial disease have mutations in three protein-encoding genes, β -myosin heavy chain (*MYH7*) in 35% to 50%, myosin-binding protein C (*MYBPC3*) in 15% to 25%, and cardiac troponin T type 2 (*TNNT2*) in 15% to 20%. In current practice, the clinical value of genetic testing is uncertain. Van Driest and colleagues⁶⁴ reported that gene-positive status did not correlate with family history of sudden cardiac death, need for myectomy, or anatomic subtype. Furthermore, specific mutations in HCM are rare; in one study, less than 2% of 293 unrelated patients had putative benign mutations, but serious clinical events developed in these patients, including sudden cardiac death, need for surgical myectomy, and cardiac transplantation.⁶⁵

Other studies suggest that certain mutations are associated with poor prognosis. For example, certain mutations in *TNNT2*, β -tropomyosin (*TPM1*), and *MYH7* may confer increased risk of sudden cardiac death. Olivetto and coworkers reported that identification of myofilament-positive patients through genetic testing predicted a fourfold increase in the risk of the combined endpoint of cardiovascular death, nonfatal stroke, or progression to New York Heart Association (NYHA) class III or class IV symptoms.⁶⁶ Mutations were associated with more severe systolic and diastolic LV dysfunction, and adverse clinical events occurred irrespective of whether the involved myofilament was thin, intermediate, or thick.

A potential benefit of genetic analysis is the preclinical diagnosis in patients with a family history of sudden cardiac death or in those carrying a "malignant" mutation that predisposes them to a severe phenotype. Also, it may be useful to know the precise genetic defect in HCM among asymptomatic family members who carry the mutation and might be at risk of sudden cardiac death.

In addition to variability in clinical course and risk of sudden cardiac death, the phenotype of HCM shows considerable diversity in the severity and distribution of hypertrophy (asymmetrical, concentric, apical), penetrance, and age at onset. This variability may be explained partially by patients who are compound heterozygotes and by the coexistence of other diseases that predispose to hypertrophy.

PATHOPHYSIOLOGY

Diastolic Dysfunction

Diastolic dysfunction with elevation of the LV end-diastolic pressure is the principal pathophysiologic finding in HCM. The resulting increase in left atrial and pulmonary venous pressures accounts for the common symptoms of effort dyspnea and limited aerobic capacity.

With worsening diastolic function, LV filling becomes more dependent on atrial contraction, and occurrence of atrial arrhythmias, especially atrial fibrillation, can cause an acute and profound decrease in cardiac output and worsening of symptoms.⁶⁷

Abnormal myocardial relaxation has been observed in patients with HCM before the development of symptoms. The increased chamber stiffness results primarily from increased wall thickness, but there are other factors of surgical importance that aggravate intrinsic diastolic dysfunction related to LV hypertrophy.

LVOT obstruction has a direct effect of increasing end-diastolic pressure and an indirect effect through the often associated mitral regurgitation. Thus, whereas surgical myectomy has a minimal immediate effect on overall LV mass, symptoms related to diastolic dysfunction are immediately improved when outflow gradients and mitral regurgitation are relieved. A secondary effect of septal myectomy on diastolic function is regression of hypertrophy, as discussed later.

In some patients, concentric ventricular hypertrophy is so severe that muscle mass encroaches on the ventricular cavity and reduces normal cavity size. This is particularly striking in patients with the apical form of HCM, in which the distal third to distal half of the left ventricle may be obliterated (during diastole and systole) by muscle. Surgical remodeling by apical myectomy may increase end-diastolic volume and thus improve diastolic function.

Left Ventricular Outflow Obstruction

Surgical treatment of HCM consists primarily of relief of LVOT obstruction. As discussed before, obstruction results from dynamic narrowing of the subaortic area, which in turn is caused by protrusion of the hypertrophied septum in apposition with the anterior leaflet of the mitral valve. Previously, there was debate on the importance of outflow tract obstruction as a mechanism for symptoms in patients with HCM because of the lability of the finding and the question of catheter entrapment when gradients were measured by invasive catheterization.⁶⁸ It is now recognized that outflow obstruction is much more common than previously thought, correlates importantly with development of symptoms, and may negatively influence long-term survival.

Maron and colleagues documented resting outflow tract gradients of 50 mm Hg or greater in 37% of 320 patients with HCM and, more important, found exercise-induced gradients (mean 80 ± 43 mm Hg) in an additional 106 patients; thus, as many as 70% of patients with HCM who come to clinical evaluation will have significant outflow tract obstruction.⁶⁹ Another important finding in this study was the relative unreliability of the Valsalva maneuver (sensitivity 40%) compared with exercise Doppler echocardiography in detecting these dynamic gradients. Latent obstruction can also be documented during hemodynamic catheterization by isoproterenol challenge, and the technique may be useful in patients who are unable to exercise or in patients in whom reliable Doppler echocardiographic signals cannot be measured.⁷⁰

Mitral Valve Regurgitation

Accelerated blood flow near the hypertrophied basal septum pushes the mitral leaflet at the same time that there may be “suction” forces that contribute to the systolic anterior motion of the mitral valve. Thus, leaflet coaptation is reduced, producing variable degrees of posteriorly directed mitral regurgitation. If the mitral regurgitant jet is directed anteriorly, primary mitral valve disease such as a flail or prolapsing segment should be suspected. As is true with outflow gradients, the degree of mitral regurgitation is often dynamic. Symptomatic patients with moderate or severe degrees of mitral regurgitation associated with HOCM are excellent candidates for operation because the mitral regurgitation and associated symptoms (dyspnea and fatigability) are almost always abolished or significantly improved with adequate septal myectomy.

Intrinsic mitral valve disease may contribute to valvular regurgitation in patients with HOCM. Rupture of chordae with resultant leaflet prolapse can precipitate congestive heart failure, and hemodynamics may worsen if HCM is not recognized and patients are managed medically with afterload reduction.⁷¹

CLINICAL PRESENTATION AND DIAGNOSTIC CRITERIA

Symptoms

Although some children and adolescents present with cardiac limitations, most patients remain asymptomatic until young adulthood or middle age. The onset of symptoms parallels development of outflow tract obstruction, and limitation is gradual, manifested first by fatigability and then by effort dyspnea, angina, and syncope or presyncope. As discussed previously, dyspnea is caused by LV diastolic dysfunction and variable degrees of mitral regurgitation. Autonomic dysfunction, which is present in approximately 25% of patients with HCM, may also contribute to poor exercise capacity; it is manifested by a failure to increase systolic blood pressure by 20 mm Hg during exercise or an actual decline in blood pressure during exertion.

Although obstructive coronary artery disease may coexist, angina is most likely explained by the combination of increased LV wall thickness (increased myocardial oxygen demand) and decreased capillary network (decreased myocardial oxygen supply) in addition to provoking factors such as increased heart rate and increased afterload.

Signs

In HCM patients without obstruction, clinical findings are those of LV hypertrophy. For patients with obstruction, it is important to differentiate dynamic obstruction from fixed obstruction as occurs with valvular aortic stenosis or congenital membranous subaortic stenosis. Auscultation in patients with HOCM reveals the classic crescendo-decrescendo murmur heard best near the left

sternal border, which peaks in mid to late systole and usually ends before the second heart sound. The murmur can radiate across the precordium, but in contrast to valvular aortic stenosis, radiation to the carotid arteries is uncommon. Mitral regurgitation may produce a separate holosystolic murmur audible at the apex. With dynamic outflow obstruction, the carotid pulsation is brisk and bifid. If there is severe hypertrophy, a fourth heart sound may be heard.

Dynamic auscultation can differentiate the murmur of HCM from that of valvular aortic stenosis and mitral regurgitation. Maneuvers such as the Valsalva or stand-squat-stand, which decrease the LV volume, will increase the dynamic gradient and the intensity of the murmur. Other maneuvers to change the intensity of the murmur include leg raising to increase preload and the inhalation of amyl nitrate to decrease afterload and increase heart rate.

Electrocardiography and Chest Radiography

In HCM with obstruction, the electrocardiogram characteristically shows LV hypertrophy with a strain pattern, and Q waves may be present. Electrocardiographic evidence of left atrial enlargement is common, as is a bundle branch block pattern (especially after myectomy). After alcohol septal ablation, a right bundle branch block is commonly observed. With the apical form of HCM, the electrocardiogram shows a distinctive pattern of diffuse symmetrical T wave inversions across the precordium.

Most patients with HCM have normal sinus rhythm, but continuous monitoring will show a high incidence of supraventricular tachycardia (46%), premature ventricular contractions (43%), and nonsustained ventricular tachycardia (26%).⁷² Atrial fibrillation develops in up to a quarter of patients, and onset of atrial fibrillation often precipitates symptoms because of loss of atrial contraction and impaired filling of the left ventricle.

Findings on chest radiography are those of LV hypertrophy and pulmonary venous congestion, and enlargement of the pulmonary artery may be apparent in patients with congestive heart failure.

Echocardiography

Two-dimensional and Doppler echocardiography is the essential tool for the diagnosis of HCM, providing information on ventricular morphology, hemodynamics, and valve function. The most common pattern of hypertrophy is diffuse involvement of the ventricular septum. In patients with HCM, average maximal LV wall thickness is 20 to 22 mm, and in 5% to 10% of patients, LV wall thickness is dramatically increased, measuring 30 to 50 mm.⁷² Morphology of the septum appears to vary according to age, and older patients with HCM often demonstrate a sigmoid configuration.⁷³

The echocardiographic findings of increased wall thickness should prompt a search for other causes, including systemic hypertension (especially in patients on dialysis); valvular aortic stenosis; and infiltrative and glycogen

storage diseases, such as cardiac amyloidosis, Fabry's disease, and Friedreich's ataxia.

On continuous wave Doppler echocardiography, LVOT obstruction is seen as a high-velocity, late-peaking, "dagger-shaped" signal. In patients with low velocity at rest (<3 m/sec), maneuvers such as the Valsalva, inhalation of amyl nitrate, and exercise may demonstrate latent obstruction. Presence and severity of mitral regurgitation can be determined by Doppler color flow imaging. It is important to differentiate the true outflow tract velocity from the mitral regurgitation jet.

Mitral regurgitation that results from systolic anterior motion is eccentric and directed posterolaterally during late systole. A centrally directed jet should suggest a primary leaflet abnormality contributing to valve leakage. Preoperative transesophageal echocardiography is unnecessary in most patients, but intraoperative transesophageal echocardiography is critically important for assessing results of myectomy.⁷⁴

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging is useful in identifying regions of LV hypertrophy not easily recognized by echocardiography, specifically the anterolateral free wall and the apical area.⁷⁵ In addition, magnetic resonance imaging can detect presence and severity of myocardial fibrosis, which appears to be an important risk factor for subsequent ventricular arrhythmias and sudden cardiac death.^{76,77}

Invasive Catheterization

In current practice, cardiac catheterization is rarely necessary for the diagnosis of HCM. Coronary angiography is indicated for patients with symptoms of angina and for patients at risk for coronary artery disease (strong family history, abnormal lipids, older age) who undergo myectomy. A hemodynamic study with isoproterenol provocation can be useful in identifying patients with labile obstruction gradients that cannot be elicited during echocardiography.⁷⁰

NATURAL HISTORY

Symptom Course

The clinical course of HCM is highly variable, and some patients remain free of symptoms and cardiac limitation. In many patients, however, onset of symptoms is associated with development of LVOT obstruction, and it is not clear what causes this in adult patients who have had no gradients until the fourth, fifth, or sixth decade of life. Onset of atrial fibrillation can also precipitate symptoms and predispose to systemic embolism, which occurs in 6% of patients.⁷⁸ Atrial fibrillation is noted in 30% of older patients with HCM.

Infective endocarditis may occur with HCM, and the reported incidence is 1.4 cases per 1000 person-years. The important feature is that in virtually all cases of endocarditis, there is LVOT obstruction. Indeed, among

HCM patients with obstruction, the incidence of endocarditis is 3.8 per 1000 person-years, or a 4% likelihood for development of this complication during 10 years.⁷⁹

Survival

In the general population, survival of patients with HCM is similar to that of individuals without disease, and early reports of high mortality in HCM may be explained by excess numbers of high-risk patients included in studies from tertiary referral centers.⁸⁰⁻⁸² More recent data indicate that the annual mortality rate of patients with HCM is approximately 1%, but there are several important subgroups that have a higher risk of cardiac death; indeed, HCM is the most common cause of sudden death among young athletes.^{7,83,84}

Obstructed versus Nonobstructed Hypertrophic Cardiomyopathy

Until recently, there was uncertainty and debate about the influence of LVOT obstruction on survival of patients with HCM. Convincing studies by Maron and colleagues,⁸⁵ Autore and associates,⁸⁶ and Elliott and coworkers⁸⁷ have demonstrated a strong correlation between resting outflow gradients and late risk of death. In a longitudinal study of 1101 patients with HCM, Maron and colleagues reported that patients with outflow tract obstruction (a basal gradient of at least 30 mm Hg) had a risk of death from HCM or symptom progression that was more than four times that observed among patients without obstruction (Fig. 96-3). The association of outflow tract obstruction on limiting symptoms and death was independent of other clinical variables. Of note, patients with obstruction and mild symptoms (NYHA class II) were more likely to have progression to severe symptoms or to die of heart failure than were asymptomatic patients with cardiomyopathy (Fig. 96-4).⁸⁵

An important clinical question is whether prognosis of asymptomatic HOCM patients with high gradients can be improved by septal reduction. Elliott and coworkers

FIGURE 96-3 ■ Survival of patients with hypertrophic cardiomyopathy (HCM) with and without obstruction (≥ 30 mm Hg). This analysis includes only deaths related to HCM. (From Maron MS, Olivetto I, Betocchi S, et al: Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 348:295–303, 2003.)

FIGURE 96-4 ■ Probability of progression to severe heart failure, death, or stroke in patients without obstruction and in patients with outflow tract obstruction stratified by presence or absence of symptoms. NYHA, New York Heart Association. (From Maron MS, Olivetto I, Betocchi S, et al: Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 348:295–303, 2003.)

reported that risk of sudden death is relatively low (<0.4% per year) in asymptomatic patients with LVOT obstruction and none of the recognized risk factors for sudden cardiac death, but their study demonstrated reduced survival among patients with LVOT obstruction and nonsustained ventricular tachycardia, abnormal exercise blood pressure response, family history of premature sudden death, unexplained syncope, or severe LV hypertrophy.

The prognosis of patients with latent obstruction is less clear, but a study by Vaglio and colleagues⁸⁸ suggests that the clinical course is similar to that of patients with resting obstruction. In their series, one quarter of patients required invasive therapy for relief of symptoms, and annual mortality was 2%, a rate higher than that reported for patients with HCM and no LVOT obstruction.

Use of Implantable Cardioverter-Defibrillator

Sudden cardiac death is a special concern in HCM, and there is debate about the appropriate use of implantable cardioverter-defibrillators (ICDs) for primary and secondary prevention of sudden cardiac death. In addition to prior cardiac arrest, clinical variables that appear to identify patients at increased risk of arrhythmic events (major risk factors) include nonsustained ventricular tachycardia, massive ventricular hypertrophy (wall thickness > 30 mm), hypotensive response to exercise, family history of sudden cardiac death, and unexplained syncope.⁸⁹ Other findings, such as myocardial bridging in young patients, apical aneurysms, or myocardial fibrosis detected by cardiac magnetic resonance imaging, may also increase risk of sudden death.

Consensus among experts⁹⁰ is that an ICD is strongly warranted for secondary prevention of sudden cardiac death in patients with prior cardiac arrest or sustained and spontaneously occurring ventricular tachycardia and should be considered in patients with multiple clinical risk factors and in selected patients with a single major risk factor, such as a history of sudden cardiac death in a

close relative. For patients who need ICD implantation and are referred for septal myectomy, we prefer to delay device implantation until the third or fourth day postoperatively to avoid the potential for lead dislocation if the ICD is placed immediately preoperatively.

SURGICAL TREATMENT

Indications for Operation

Septal myectomy is, in general, reserved for patients who continue to have limiting symptoms despite medical treatment. Pharmacologic therapy usually begins with β -adrenergic blocking agents, which have a negative inotropic effect and may mitigate latent outflow gradients provoked with exercise. Beta blockers are less effective in reducing resting gradients. The calcium antagonist verapamil has been used for patients with nonobstructive and obstructive HCM. The drug may improve ventricular relaxation and decreased LV contractility, but hemodynamic and electrophysiologic side effects limit long-term use. Disopyramide has negative inotropic effects and is a type Ia antiarrhythmic agent that can improve symptoms by reducing resting gradients. However, this drug also has side effects, including dry mouth and eyes, constipation, and difficulty in micturition. In addition, it increases atrioventricular nodal conduction and thus may increase ventricular rate in patients with atrial fibrillation. Although medications may ameliorate symptoms, drug therapy does not appear to decrease the probability of sudden death. In a study of 173 patients who were taking amiodarone, beta blockers, verapamil, or sotalol for treatment of symptoms, there was no difference in sudden death mortality compared with patients who were receiving no pharmacologic therapy.⁹¹ Thus, ICDs remain the primary therapy for prevention of sudden death in high-risk HOCM patients.

Technique of Operation

Operation is performed through a median sternotomy, and normothermic cardiopulmonary bypass is established in the standard fashion by use of a single, two-staged venous cannula. The aorta is cross-clamped, and cold blood cardioplegia (1000 to 1200 mL) is infused through the aortic needle vent to arrest the heart. Adequate exposure of the subaortic septum is critically important, and several maneuvers facilitate the operation. First, pericardial sutures are used only on the right side to elevate the pericardium toward the surgeon. Next, an oblique aortotomy is made slightly closer to the sinotubular ridge than is usual for aortic valve replacement, and the incision is carried through the midpoint of the noncoronary aortic sinus of Valsalva to a level approximately 1 cm above the valve annulus. The edge of the proximal aorta is held out of the way with small stay sutures, and a cardiectomy sucker is placed through the aortic valve and used to depress the anterior leaflet of the mitral valve to protect it from injury. The right aortic valve cusp is collapsed against the sinus wall, where it will usually stay. A sponge stick is used to depress the right ventricle and to rotate

the septum posteriorly, orienting the LV outflow anteriorly (Fig. 96-5).

A standard no. 10 scalpel blade is used for myectomy; incision in the septum begins just to the right of the nadir of the right aortic sinus (Fig. 96-6). The incision in the septum is made upward and then leftward over to the anterior leaflet of the mitral valve. Scissors are used to complete excision of this initial portion of myocardium. The area of septal excision is then deepened and lengthened toward the apex of the heart, and the hypertrophied septum must be excised beyond endocardial scar (Figs. 96-7 and 96-8). Trabeculations are excised, and the

myectomy site is further enlarged with the use of pituitary rongeurs. Adequate septal myectomy usually yields 3 to 12 g of muscle. Use of the sponge stick to depress the heart posteriorly will improve exposure of the distal extent of the myectomy. The aortotomy is closed, and the operation proceeds as usual.

This technique for more extended myectomy⁹² differs from the standard Morrow operation,³² in which parallel incisions create a trough in the septum that extends up to 3 cm from the aortic valve; wider excision of muscle in the immediate subaortic area improves exposure of the distal extent of the hypertrophied septum, and excision

FIGURE 96-5 ■ The subaortic septum is exposed through an oblique aortotomy extended to the base of the noncoronary sinus. The surgeon's view of the septum is improved by depressing and rotating the ventricle posteriorly with a sponge forceps. (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

FIGURE 96-6 ■ Septal excision begins just to the right of the nadir of the right aortic sinus and extends leftward toward the anterior leaflet of the mitral valve. After the initial specimen is removed, the area of septal excision should be carried toward the apex of the heart well past the endocardial scar. A wider proximal area of excision improves exposure of the more distal extent of septectomy. (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

FIGURE 96-7 ■ **A**, A common error in performing septal myectomy is inadequate length (toward the apex) of muscle excision. The bulging septum may appear to be in the immediate subaortic position after initial aortotomy, but if only this portion of the enlarged septum is removed, there may be residual obstruction, as seen by the arrow in **B**. (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

FIGURE 96-8 ■ **A**, Rotation of the ventricle posteriorly improves exposure of the septum and allows the surgeon access to the distal extent of the obstructing segment (**B**). (Adapted and used with permission of Mayo Foundation for Medical Education and Research.)

extends up to 7 cm from the aortic valve. Inadequate myectomy results more often from failure to excise sufficient length of the septum (toward the apex) than from inadequate depth of excision. The methods described have proved adequate for all patients with subaortic obstruction, and maneuvers such as anterior leaflet plication are unnecessary and potentially harmful. Mitral valve replacement is reserved for patients with intrinsic leaflet abnormalities that cannot be repaired. To confirm complete relief of the LVOT obstruction, we routinely measure simultaneous aortic and LV pressure by direct needle puncture before and after myectomy.⁹³ If the resting LVOT gradient is diminished by effects of anesthesia, premature ventricular beats are induced by stimulating the ventricle to elicit the dynamic gradient produced by the Brockenbrough phenomenon; the post-extrasystolic contraction is more forceful because of increased contractility and decreased afterload. The same maneuver is then repeated after myectomy. Transesophageal echocardiography is routinely used.⁷⁴ Intraoperative transesophageal echocardiography can identify residual mitral valve regurgitation, systolic anterior motion, and any septal defects created by excision of septal muscle.

Unroofing of coronary artery bridging is performed in selected cases, particularly young patients and those who have angina preoperatively. After identification of the coronary artery distal to the intramyocardial segment, the anterior surface of the vessel is exposed by sharp dissection that is continued proximally until the LAD reemerges onto the epicardium. The divided myocardium over the artery is usually 3 to 5 mm thick. If the course of the artery is so deep that trabeculations of the right ventricular cavity are entered, pledgeted sutures placed deep into the coronary artery repair the opening into the ventricle. We have combined unroofing of myocardial bridging of the LAD with extended septal

myectomy in more than 36 patients with satisfactory outcomes. Angina is improved, but there is no evidence to suggest that there is a survival benefit secondary to the procedure. Thus, in adult patients, unroofing of a myocardial bridge portion should be considered when a patient undergoes myectomy and has a history of angina.⁹⁴

Postoperative Care

Care of patients after myectomy is similar to care of patients who have had valve replacement for aortic stenosis. Systemic vascular resistance should be maintained at or above the normal range so that LV diastolic filling pressure and coronary perfusion pressure are maintained in the hypertrophied ventricles. Vasodilators are avoided, and continuous infusions of phenylephrine or vasopressin may be useful. It is important to maintain atrioventricular synchrony to maximize LV filling, and atrial pacing is often used. The day after operation, we restart beta-blocking medications at half the preoperative dose but do not routinely restart calcium channel blockers or disopyramide. Atrial fibrillation can be especially deleterious to cardiac output and blood pressure, and early electrical cardioversion may be necessary.

OUTCOMES

Early Results

Mortality

Risk of hospital death after isolated septal myectomy for HOCM is low: less than 1% in experienced centers (Fig. 96-9). Surgical risk may be higher among very elderly patients (particularly those with severe disabling symptoms associated with pulmonary hypertension), patients

with prior myectomy, or those requiring concomitant procedures.

Morbidity

Complications such as complete heart block requiring permanent pacemaker and iatrogenic ventricular septal perforation have become uncommon ($\leq 1\%$ to 2%).⁹⁰ Partial or complete left bundle branch block is a frequent

finding after surgical myectomy but is not associated with adverse sequelae. However, if the patient has complete right bundle branch block preoperatively, interruption of the left bundle after myectomy increases risk of complete heart block. This is particularly important in patients who have had alcohol septal ablation before operation. ElBardissi and coworkers⁹⁵ reported that risk of postoperative pacemaker insertion was 36% in patients who had alcohol septal ablation before myectomy compared with 3% for those without prior intervention.

FIGURE 96-9 ■ Operative risk of isolated septal myectomy for hypertrophic cardiomyopathy is less than 1% and approaches zero in centers with broad experience with the procedure. (From Maron BJ: Surgical myectomy remains the primary treatment option for severely symptomatic patients with obstructive hypertrophic cardiomyopathy. *Circulation* 116:196–206, 2007.)

Late Results

Symptom Relief

Improvement in symptoms and exercise capacity after myectomy is highly predictable and durable; more than 90% of severely symptomatic patients have improvement of two or more function classes. Indeed, as illustrated in Figure 96-10, relief of outflow gradients by myectomy is equally effective in improving limitation caused by dyspnea, angina, or syncope.⁹⁶ Importantly, symptomatic benefit of myectomy is directly related to reducing the basal outflow gradient and mitral regurgitation and restoring normal LV systolic and end-diastolic pressures (in more than 90% of patients), which in turn may also favorably influence LV diastolic filling and myocardial ischemia. Relief of the gradient may decrease left atrial size and the subsequent risk for development of atrial fibrillation.

The outcome of patients with latent LVOT obstruction preoperatively is especially instructive. Often operation is withheld in these symptomatic patients because the resting LVOT gradient is less than 30 mm Hg, and

FIGURE 96-10 ■ Symptomatic status of patients with hypertrophic obstructive cardiomyopathy before (Pre) and after (Post) septal myectomy. Relief of obstruction improves angina, dyspnea, and syncope or presyncope. CHF, Congestive heart failure. (From McCully RB, Nishimura RA, Tajik AJ, et al: Extent of clinical improvement after surgical treatment of hypertrophic obstructive cardiomyopathy. *Circulation* 94:467–471, 1996.)

disability is presumed to be caused by diastolic dysfunction. But provocative maneuvers frequently elicit higher gradients and systolic anterior motion (SAM)-related mitral regurgitation that correlate with symptoms. Indeed, in our surgical practice, 30% of patients undergoing septal myectomy have latent obstruction with resting gradients less than 30 mm Hg, and postoperatively, NYHA functional class improves dramatically and to a similar extent as seen in patients with high resting LVOT gradients.⁹⁷

Late recurrence of large resting LV outflow gradients is very uncommon after successful myectomy in either adults or children with HOCM, and this is in contrast to patients who have surgery for relief of congenital membranous subaortic stenosis.⁴⁶ The most common causes of recurrent symptoms and obstruction are limited myectomy at the initial operation, midventricular obstruction, and anomalies of papillary muscles. Most often, inadequate myectomy at initial operation is a result of failure to extend the myectomy far enough toward the apex of the heart.⁹⁸

SURVIVAL

Septal myectomy is usually performed for relief of symptoms, but there is evidence that operation may improve survival of patients with HOCM. In a report by Ommen and coworkers,⁹⁹ late survival of 289 patients with HOCM undergoing septal myectomy was 98%, 96%, and 83% 1 year, 5 years, and 10 years postoperatively, and these survival rates were similar to those of an age- and sex-matched U.S. population and to those of HCM patients without obstruction (Fig. 96-11). In the same study, myectomy patients had superior survival free from all-cause mortality ($P < 0.001$), HCM-related mortality ($P < 0.001$), and sudden cardiac death ($P = 0.003$) compared with those of nonsurgical HCM patients with obstruction (Fig. 96-12), and on multivariable analysis, performance

of myectomy had a strong, independent association with survival (hazard ratio, 0.43; $P < 0.001$).

Studies also suggest mechanisms whereby relief of LVOT gradients might improve survival. The extent of LV hypertrophy is an important determinant of survival in patients with HCM,¹⁰⁰ and successful myectomy results in some regression of LV hypertrophy.^{101,102} Thus, patients with the obstructive form of HCM may have an additive burden of ventricular hypertrophy caused by pressure overload that is relieved by successful myectomy. It is interesting to note that whereas extent of LV hypertrophy is a risk factor for death in natural history studies of HCM, following myectomy, degree of hypertrophy preoperatively does not predict outcome.¹⁰³

Additional insights on improved survival of myectomy patients come from McLeod and associates,¹⁰⁴ who reviewed patients with HCM who had received ICDs. During follow-up (median, 4.5 years), 12 patients (17%) in the nonmyectomy group and only one patient (2%) in the myectomy group had appropriate ICD discharges (Fig. 96-13). The average annualized event rate was 4.3% per year in the nonmyectomy group compared with 0.24% per year after myectomy ($P = 0.004$). Thus, surgical myectomy and relief of outflow gradient is associated with a marked reduction in the incidence of appropriate ICD discharges and risk of sudden cardiac death.

The potential benefit of septal myectomy on patient survival is supported also by postoperative outcome of patients who present with syncope. The presence of syncope despite medical therapy in patients with HCM is considered an indication for surgical myectomy, and Orme and associates^{104a} documented that at median follow-up of approximately 5 years, the recurrence rate of syncope in myectomy patients was 11% compared to 40% in a medically treated group matched for other risk factors. Further, the 10-year survival rate was greater for patients who had undergone surgical myectomy than for the medically treated patients (82% vs. 69%).

FIGURE 96-11 ■ Survival of patients with hypertrophic obstructive cardiomyopathy after septal myectomy is similar to that of an age- and gender-matched population. (From Ommen SR, Maron BJ, Olivotto I, et al: Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 46:470–476, 2005.)

FIGURE 96-12 ■ Survival free from all-cause mortality in three hypertrophic cardiomyopathy patient subgroups: Mayo Clinic surgical myectomy ($n = 289$), nonoperated with obstruction ($n = 228$), and nonobstructive ($n = 820$). Myectomy versus nonoperated obstructive hypertrophic cardiomyopathy, $P < 0.001$; myectomy versus nonobstructive hypertrophic cardiomyopathy, $P = 0.8$. (From Ommen SR, Maron BJ, Olivotto I, et al: Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 46:470–476, 2005.)

COMPARISON TO SEPTAL ARTERY ABLATION

Septal reduction can be achieved by selective infarction of septal branches of the LAD, and the advantages of avoiding surgical incision and hospitalization are obvious. In a review of alcohol septal ablation from 42 published

FIGURE 96-13 ■ Implantable cardioverter-defibrillator (ICD) discharge rates among patients with hypertrophic cardiomyopathy who had septal myectomy compared with nonmyectomy patients. Average annualized ICD discharge rates of 0.24% in the myectomy group compared with 4.3% in the nonmyectomy group ($P = 0.004$). (From McLeod CJ, Ommen SR, Ackerman MJ, et al: Surgical septal myectomy decreases the risk for appropriate implantable cardioverter defibrillator discharge in obstructive hypertrophic cardiomyopathy. *Eur Heart J* 28:2583–2588, 2007.)

studies (2959 patients), resting LVOT gradient decreased from 65 mm Hg to 16 mm Hg ($P < 0.001$), basal septal diameter reduced from 21 mm to 14 mm ($P < 0.001$), and hospital mortality was 1.5%.¹⁰⁵ However, the incidence of complete heart block requiring permanent pacemaker was 11%, and other important complications included coronary dissection (1.8%), pericardial effusion (0.6%), ventricular fibrillation (2.2%), stroke (1.1%), new right bundle branch block (46%), and new left bundle branch block (6.5%). Also, symptoms persisted in 11% of patients, re-do alcohol ablation was required in 6.6%, and surgical myectomy was necessary in 2.0%. Thus, whereas this procedure is less invasive, it is not without significant morbidity and mortality.

Because of unfavorable coronary anatomy, some patients with HOCM are not candidates for alcohol septal ablation.¹⁰⁶ Also, concern has been raised about the potential long-term risk of sudden death related to arrhythmogenic substrate from the resulting septal scar. Cardiac magnetic resonance imaging demonstrates that in most patients, alcohol septal ablation causes transmural tissue necrosis, located more inferiorly in the basal septum than myectomy; the infarct usually extends into the right ventricular side of the septum and sometimes spares the basal septum, leading to residual gradients at follow-up (Fig. 96-14).¹⁰⁷ In a nonrandomized comparative study, Sorajja and colleagues¹⁰⁸ reported that in-hospital complication rate is higher with ablation than with myectomy, and that in patients 65 years of age or younger, symptom relief is better after myectomy.

Thus, alcohol septal ablation is an option for patients who may have increased risk for operation, but septal

FIGURE 96-14 ■ Cardiac magnetic resonance image after septal myectomy versus septal ablation. *Top panels*, Long-axis views before (Pre) and after (Post) septal myectomy. The portion of basal septum evident in this plane, projecting into the left ventricular (LV) outflow tract, has been excised at myectomy (arrows). *Bottom panels*, Long-axis views before (left) and 5 months after (right) septal ablation. Ablation has spared the most proximal portion of basal septum. AML, Anterior mitral leaflet; Ao, aorta; LA, left atrium; RV, right ventricle. myectomy remains the gold standard for patients with HCM and severe LV outflow obstruction who are refractory to maximal medical therapy.^{61,90}

SPECIAL SUBGROUPS

The preceding discussion has focused on surgical treatment of patients with HCM and subaortic obstruction, and, whereas these patients constitute most of the patients considered for surgical treatment, other HCM patients with different ventricular morphology and pathophysiology may benefit from operation. Midventricular obstruction in HCM is less common than subaortic obstruction, has a different pathophysiologic mechanism, and, in untreated patients, may have a worse prognosis.¹⁰⁹ Unlike subaortic obstruction, related to systolic anterior motion of the mitral valve, midventricular obstruction is caused by systolic narrowing of the mid ventricle with apposition of the septum and papillary muscles. Secondary mitral valve regurgitation is uncommon and is not a part of the pathophysiology of symptoms such as dyspnea, but patients with HCM and midventricular obstruction may develop apical pouches/aneurysms that can lead to ventricular arrhythmias or thromboembolism.^{110,111}

The decision for myectomy in patients with midventricular obstruction is often confounded by uncertainty whether limiting symptoms are due to the intraventricular gradient or to diastolic dysfunction (or both). Also, there is a wide spectrum of phenotypes, and some patients will have both subaortic obstruction (with systolic anterior motion of the mitral leaflets) and midventricular obstruction.

In our experience, midventricular obstruction is most easily exposed through a transapical incision, and the contact lesion that is uniformly present guides excision of the septum.¹¹² Among 51 patients having operation for HCM with midventricular obstruction, a transapical approach was used in 32 patients and a combined transapical and transaortic approach was used in 19 patients. In 13 patients, an apical aneurysm or pouch was repaired at the time of midventricular myectomy. No early deaths or complications related to the apical incision have resulted.

Thromboembolism
Right Ventricular Failure
Arrhythmia
Aortic Insufficiency
Device Malfunction

SUMMARY

Mechanical circulatory support (MCS) has become the standard of care for patients with refractory, end-stage heart failure.¹⁻⁷ A landmark trial in MCS demonstrated the superiority of a left ventricular assist device (LVAD) over optimal medical therapy with respect to improving survival and quality of life in this subgroup of patients.¹ Over the past decade, there has been a significant evolution in MCS device-related technologies. Devices have undergone substantial modifications in an effort to

improve survival while on support, increase durability, and limit device-related infections, device thrombosis, device malfunction, and perioperative bleeding.³⁻⁵ With improvements in device design yielding devices that can be implanted as destination therapy, the number of durable LVAD implants has dramatically increased in the United States every year (Fig. 97-1).⁶

Current MCS devices can be divided into the following subcategories on the basis of their features:

FIGURE 97-1 ■ Number of durable mechanical circulatory support device implants per year by device strategy. (Reproduced with permission from INTERMACS, *Quarterly Statistical Report*, 3rd quarter, 2013.)

short-term versus long-term devices, paracorporeal versus intracorporeal devices, pulsatile versus continuous flow devices, full versus partial support devices, and assist devices versus complete heart replacement (i.e., total artificial heart [TAH]). The indications for implantation of a mechanical device have expanded over time to include acute cardiogenic shock, bridge to transplant (BTT), bridge to candidate (BTC), and destination therapy (DT).^{1,3,6,7} This chapter presents a complete overview of MCS, including a historical perspective, indications for MCS, important factors related to patient selection, types of devices, results using MCS, surgical technique, post-operative management, and complications that occur with MCS.

HISTORICAL PERSPECTIVE

Dr. Michael DeBakey implanted the first mechanical assist device in 1963 in a patient with postcardiotomy shock after an aortic valve replacement. With growing interest in MCS, the Artificial Heart Program was founded in 1964. In 1966, DeBakey reported the first successful bridging to recovery with a ventricular assist device (VAD), also in a patient with postcardiotomy shock. The duration of support in this patient was 10 days.

In 1970, the Artificial Heart Program evolved into the Medical Devices Applications Branch of the National Heart and Lung Institute, with the primary focus of developing short- and long-term VADs as well as a TAH for heart replacement therapy. Dr. Denton Cooley reported the first successful bridging to transplant using MCS in 1978. In 1980, the currently named National Heart Lung and Blood Institute (NHLBI) accepted proposals by Abiomed, Baxter, Thermo Cardiosystems, and

Thoratec to develop VADs and the TAH. The first successful implantation of a heart replacement therapy, a TAH with the Jarvik-7-100, was reported in 1984. However, this device was removed from clinical practice in 1991 because of a relatively high incidence of device-related complications, such as thromboembolic events and infection.

With concurrent advancements in assist device technology, the U.S. Food and Drug Administration (FDA) approved the use of a mechanical assist device as a BTT in 1994—the first of which was HeartMate (Thoratec Corp., Pleasanton, CA), developed by Thermo Cardiosystems. It soon became clear to the cardiac surgery community that implantation of LVADs could salvage patients who were otherwise nonsalvageable and could also improve the quality of life of patients with advanced heart failure.

A major victory for MCS came in 2001 with the results of the REMATCH trial.¹ This prospective, randomized trial of patients with end-stage heart failure who were not eligible for transplantation demonstrated a significant survival advantage for patients who underwent implantation of a mechanical assist device as compared with those receiving optimal medical therapy. The study, however, also highlighted various complications of mechanical support, such as bleeding, infection, stroke, device malfunction, and development of right heart failure, which became a primary focus for device companies and engineers in subsequent years.

The emergence of newer generation VADs with a continuous flow pump driven by a rotary pump represented a further step in this field. A randomized trial demonstrated that a continuous flow pump significantly improved 2-year survival and device-related morbidity as compared with a pulsatile device.³ Since the approval of the continuous flow VADs for both transplant-eligible

(BTT) and transplant-ineligible patients (DT), the number of patients receiving MCS device therapy has been growing rapidly.

As VAD therapy entered the mainstream, INTERMACS (Interagency Registry for Mechanically Assisted Circulatory Support)—a national registry for patients who are receiving MCS devices—was established in 2006. This registry was devised as a joint effort of the NHLBI, the Centers for Medicare and Medicaid Services (CMS), the FDA, clinicians, scientists, and industry representatives in conjunction with the University of Alabama at Birmingham and the United Network for Organ Sharing (UNOS). Analysis of the data collected is expected to facilitate further improvements in patient evaluation and management.

IMPLANT STRATEGIES FOR MECHANICAL CIRCULATORY SUPPORT

When considering MCS placement, five broad indications can be defined with regard to the clinical intent at the time of implantation. Complex decisions about candidacy for each strategy should be made by an experienced, multidisciplinary team including surgeons and cardiologists. This process is particularly important in ensuring appropriate selection of the patient, timing for device placement, and device to use.

Bridge to Transplant

BTT is a strategy for patients actively listed for heart transplant who would not survive or would develop end-organ dysfunction as a result of low cardiac output before an organ becomes available. While the patient remains on the waiting list, insertion of a durable LVAD can improve survival, functional status, and quality of life.

Destination Therapy

DT is a strategy for patients requiring long-term, lifelong circulatory support who are not eligible for heart transplant because of relative or absolute contraindications.

Bridge to Candidacy

MCS may be used for patients who are not currently listed for heart transplant, with no absolute or a permanent contraindication to transplant. MCS may allow these patients to be eligible for transplant by improving their end-organ function and nutrition, decreasing pulmonary vascular resistance, as well as resolution of comorbidities or lifestyle-related problems (e.g., weight loss, smoking cessation).

Bridge to Decision

In circumstances when a patient is in acute cardiogenic shock, it may not be possible to determine the candidacy for transplant, long-term VADs or myocardial recovery. Additionally, the patient may or may not have multisystem organ failure, and the patient's neurologic status may

or may not be known. A short-term MCS may be used to stabilize the patient's condition and to assess reversibility, as a bridge to more definitive therapies. The next step can be planned while the patient is on the MCS.

Bridge to Recovery

MCS may be used as a temporary circulatory support to unload the ventricle. During this time, MCS use may enhance myocardial recovery from an acute injury enough to wean off the device without the need for transplant.

PATIENT SELECTION

Careful patient selection—a critical element in achieving good clinical results with MCS—requires the evaluation of heart failure severity and the assessment of operative risk and comorbidities.

Common indicators of advanced heart failure for referral for MCS include New York Heart Association (NYHA) class IIIb-IV symptoms, frequent rehospitalizations for heart failure, or unresponsiveness to medical therapies (including neurohormonal antagonists and diuretics), recurrent/refractory ventricular tachyarrhythmia, inotrope dependence, unresponsiveness to cardiac resynchronization therapy, end-organ dysfunction as a result of low cardiac output, peak oxygen consumption less than 14 mL/kg/min, or 6-minute walk distance less than 300 m.⁸ The Seattle Heart Failure Model can be used to estimate a heart failure patient's expected mortality in the next 1 to 2 years and identify patients who might benefit from LVAD support.⁹

The INTERMACS registry classifies heart failure patients into seven clinical profiles based on their signs and symptoms (Table 97-1). These profiles also help to define illness acuity and severity and to assess the operative risk.⁶ The INTERMACS data showed that the proportion of patients in progressive cardiac decompensation (level 2) or cardiogenic shock (level 1) at the time of implantation of a durable LVAD has decreased from approximately 64% before 2011 to slightly less than 54% in 2012. This is because the patients in INTERMACS levels 1 and 2 have a 5% to 8% decrease in 1-year survival rate compared with patients in other INTERMACS levels (Fig. 97-2). Generally, for patients in INTERMACS level 1, placement of a durable VAD is not recommended because these patients are often compromised by end-organ damage, uncertain neurologic status, infection, or major coagulopathy. Therefore, short-term MCS should be applied in these patients as a bridge to decision (BTD) or recovery. Conversely, patients in INTERMACS level 6 or 7 (NYHA class III) are, in general, considered “too well” for MCS placement. Currently, patients in INTERMACS levels 2, 3, or 4 are likely to be appropriate candidates for a durable LVAD implantation.

It is also important to identify those patients with significant right ventricular (RV) dysfunction before LVAD implantation, because RV failure after LVAD implantation can be a fatal complication.¹⁰⁻¹³ The implantation of an LVAD can decrease RV afterload by reducing

TABLE 97-1 INTERMACS Profile Descriptions

Profile 1: Critical Cardiogenic Shock

Patients with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion, often confirmed by worsening acidosis and/or lactate levels. "Crash and burn."

Profile 2: Progressive Decline

Patient with declining function despite intravenous inotropic support; may be manifest by worsening renal function, nutritional depletion, inability to restore volume balance. "Sliding on inotropes." Also describes declining status in patients unable to tolerate inotropic therapy.

Profile 3: Stable But Inotrope Dependent

Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support (or a temporary circulatory support device or both) but demonstrating repeated failure to wean from support due to recurrent symptomatic hypotension or renal dysfunction. "Dependent stability."

Profile 4: Resting Symptoms

Patient can be stabilized close to normal volume status but experiences daily symptoms of congestion at rest or during ADLs. Doses of diuretics generally fluctuate at very high levels. More intensive management and surveillance strategies should be considered, which may in some cases reveal poor compliance that would compromise outcomes with any therapy. Some patients may shuttle between 4 and 5.

Profile 5: Exertion Intolerant

Comfortable at rest and with ADLs but unable to engage in any other activity, living predominantly within the house. Patients are comfortable at rest without congestive symptoms but may have underlying refractory elevated volume status, often with renal dysfunction. If underlying nutritional status and organ function are marginal, patient may be more at risk than INTERMACS 4 and require definitive intervention.

Profile 6: Exertion Limited

Patient without evidence of fluid overload is comfortable at rest and with ADLs and minor activities outside the home but fatigues after the first few minutes of any meaningful activity. Attribution to cardiac limitation requires careful measurement of peak oxygen consumption, in some cases with hemodynamic monitoring to confirm severity of cardiac impairment. "Walking wounded."

Profile 7: Advanced NYHA III

A placeholder for more precise specification in future, this level includes patients who are without current or recent episodes of unstable fluid balance, living comfortably with meaningful activity limited to mild physical exertion.

ADLs, Activities of daily living; NYHA, New York Heart Association.

pulmonary artery pressures. However, at the same time, increasing cardiac output with an LVAD support may increase systemic venous return to a diseased RV that may not be able to accommodate the additional volume. Furthermore, LV pressure unloading by an LVAD can cause the interventricular septum to shift leftward,

leading to geometric changes in the RV that reduce RV function, exacerbating tricuspid regurgitation. The presence of depressed RV myocardial function can be determined from preoperative hemodynamic indices, including central venous pressure, pulmonary artery pressure, cardiac output, transpulmonary pressure gradient, pulmonary vascular resistance, and RV stroke work index (RVSWI).¹⁰⁻¹³ The RVSWI can be calculated using the following formula: (mean pulmonary artery pressure – mean central venous pressure) × stroke volume ÷ body surface area. Patients with high pulmonary artery pressure and normal central venous pressure (high RVSWI) are at lower risk of postoperative RV failure because the RV is able to generate sufficient pressure. A preoperative echocardiographic assessment of RV function is also important. Attention should be paid to RV dilation, contractility, and degree of tricuspid regurgitation. Numerous studies have attempted to identify the risk factors for the development of RV failure after LVAD placement. The most recent study demonstrated that preoperative predictors of RV failure after implantation of a contemporary continuous flow LVAD included central venous pressure/pulmonary capillary wedge pressure ratio of greater than 0.63, need for preoperative ventilator support, and blood urea nitrogen level greater than 39 mg/dL.¹² Univariate predictors also included RVSWI less than 300 mm Hg × mL/m², central venous pressure greater than 15 mm Hg, and elevated white blood cell count. For patients at a significantly high risk of RV failure, planned biventricular assist device placement should be indicated.¹⁴

Pulmonary hypertension with an elevated pulmonary vascular resistance (>5 wood units) should not be considered an absolute contraindication to MCS. Modern selective pulmonary vasodilators such as sildenafil can reduce pulmonary pressures. In addition, patients who undergo LVAD implantation usually have improved pulmonary vascular resistance.^{15,16} The LVAD can be considered as a BTC in possible transplant candidates with fixed pulmonary hypertension.

Contraindications for device implantation include irreversible end-organ failure, particularly renal failure and hepatic failure, which are uniformly independent predictors of poor outcome.^{6,17-21} Severe, unrecoverable neurologic injury is also a contraindication for device implantation. Systemic sepsis poses a significant risk to patients undergoing LVAD implantation because it can cause a profound refractory vasodilatory state or lead to an increased incidence of device-related infections, such as device endocarditis.^{22,23}

In the pulsatile flow era, numerous studies have identified independent predictors of adverse outcome.^{21,24-26} The common denominator among these independent predictors of mortality is end-organ failure, such as respiratory failure requiring mechanical ventilation, renal failure requiring dialysis, ischemic hepatitis with markedly elevated transaminases, and diffuse coagulopathy resulting from malfunctioning clotting mechanisms. In the revised Columbia screening scale, the following clinical factors were identified as preoperative independent predictors of adverse outcome: mechanical ventilation, prior cardiectomy, prior LVAD implantation, central

FIGURE 97-2 ■ Survival after durable mechanical circulatory support device implantation by INTERMACS level. *BiVAD*, Biventricular assist device; *BTT*, bridge to transplant; *DT*, destination therapy; *LVAD*, left ventricular assist device. (Reproduced with permission from Kirklin JK, Naftel DC, Kormos RL, et al: Fifth INTERMACS annual report: risk factor analysis from more than 6,000 mechanical circulatory support patients. *J Heart Lung Transplant* 32:141–156, 2013.)

venous pressure of greater than 15 mm Hg, and prothrombin time of longer than 16 sec.¹⁵ Each factor was given a statistically weighted score, with a score of higher than 5 being associated with a 46% mortality rate and a score of 5 or lower being associated with a 12% mortality rate.

In the continuous flow era, from the analysis of 1122 patients receiving the HeartMate II as a BTT or DT, preoperative predictors of 90-day mortality were older patients, greater degree of hypoalbuminemia, renal dysfunction (higher creatinine), coagulopathy (higher INR), and implant surgery at less experienced centers. Based on the calculated risk score from these factors, mortality rates in the low, medium, and high-risk score groups were 4%, 16%, and 29%, respectively.²⁷ From the INTERMACS registry data, risk factors for mortality included older age, INTERMACS level 1 and 2, DT, renal dysfunction, RV dysfunction, and surgical complexity.⁶

Poor preoperative hepatic function has also been demonstrated to be an independent predictor of mortality after LVAD implantation.^{17,21,24,26} Decreased hepatic synthetic function increases the chance of developing a diffuse coagulopathy intraoperatively and postoperatively, which can cause RV failure secondary to increased transfusion requirements of blood products. The Model of End-stage Liver Disease (MELD) score calculated based on serum bilirubin, creatinine, and INR values is reported to be useful in identifying LVAD candidates at high risk for perioperative bleeding and mortality.^{28,29} Optimization of hemodynamics with reduction of central venous pressure and improvement of cardiac output should be pursued before LVAD implantation to improve hepatic congestion and increase hepatic blood flow.

Severe renal dysfunction was associated with a major reduction in early survival after durable VAD

implantation.^{6,18,20,21,26,27} The incremental effect of worsening renal dysfunction was shown by assigning “moderate” renal dysfunction to patients with a creatinine level greater than 2 mg/dL or blood urea nitrogen level greater than 60 mg/dL, and “severe” renal dysfunction to patients requiring dialysis near the time of device implantation.⁶ Although renal dysfunction caused by low cardiac output or renal vein congestion generally improves after MCS placement, caution should be paid in a patient with severe intrinsic renal disease such as chronic hypertension or diabetes mellitus. Patients with end-stage renal disease requiring dialysis should not be considered for durable LVAD implantation, because of their increased risk of infection.

Preoperative nutrition status assessment is also important.³⁰ Patients with cardiac cachexia are predisposed to poor healing, impaired immunity, and infection, which are generally associated with high mortality.^{26,27} In contrast, obesity is not a contraindication to using a continuous flow LVAD, although patients with a body mass index higher than 35 kg/m² are not eligible for heart transplant.³¹ These devices can provide sufficient cardiac output support to meet the metabolic demands of obese patients.^{32,33}

To assess the patient’s ability to understand VAD care, an investigation of prior psychiatric disorders, history of drug and alcohol abuse, compliance, and cognitive function needs to be conducted. Furthermore, adequate family/caregiver, financial, and environmental support are additional factors for determining potential LVAD candidates.³⁴

Although it is important not to delay durable VAD implantation to the point of significant end-organ dysfunction, it is beneficial to optimize a relatively stable patient preoperatively. This may include hemodynamics

optimization with diuretics, inotropes, short-term MCS (coagulopathy correction) with vitamin K, platelets, or fresh-frozen plasma, and nutrition management. With appropriate patient selection and timing of LVAD implantation, it is possible to achieve excellent results with relatively low associated morbidity and mortality.

TYPES OF DEVICES

Short-Term Mechanical Circulatory Support

Recent innovation of continuous flow technology contributes to the development of various types of short-term MCS, which can be distinguished by the method of placement (i.e., percutaneous or surgical). The current options for percutaneous circulatory support include intra-aortic balloon pump (IABP), extracorporeal membrane oxygenation (ECMO), the Impella, and TandemHeart. Surgical options include the CentriMag (Thoratec, Pleasanton, CA) ventricular support system. Each of these devices is designed for short-term use.

Percutaneous Devices for Short-Term Mechanical Support

Intra-Aortic Balloon Pump. Insertion of an IABP was first reported by Kantrowitz in 1968. It has since become one of the most common forms of mechanical support for the failing heart. It is commonly used for high-risk percutaneous coronary intervention (PCI), acute cardiogenic shock after myocardial infarction (MI), complications after MI such as a ruptured papillary muscle, cardiomyopathy, and preoperative optimization of an MI patient who is awaiting coronary artery bypass grafting (CABG).³⁵ Its mechanism of action involves inflation of the balloon in the descending aorta during diastole, which reduces afterload, increases coronary artery perfusion and pressure, improves myocardial oxygen supply, and decreases myocardial oxygen demand.³⁶ Counterpulsation can be synchronized with either an electrocardiogram or an arterial waveform. Vascular complications of

the IABP include femoral artery rupture, pseudoaneurysm, descending aortic dissection, as well as distal ischemia as a result of impedance of forward flow.³⁷

Extracorporeal Membrane Oxygenation. For patients in circulatory and respiratory failure, ECMO is a viable option. This system uses a centrifugal pump with an oxygenator and a heat exchanger in the circuit, yielding complete cardiopulmonary bypass. A venovenous ECMO is used for respiratory failure with preserved native heart function. To support the failing heart, a venoarterial (VA) ECMO is required (Fig. 97-3). A VA-ECMO system can provide full circulatory support with over 4.5 liter/min flow and rapidly improve tissue oxygenation. The major advantage of this system is the quick and easy percutaneous insertion of inflow and outflow cannulas—generally via the femoral artery and vein. Major disadvantages include infection, bleeding, and complications related to vascular access. Most survival data reported with ECMO have been in the pediatric literature.³⁸ The Extracorporeal Life Support Organization (ELSO) registry has accumulated data on more than 50,000 ECMO cases from more than 220 ECMO centers worldwide, including approximately 2300 cases of adult cardiac failure. In 2012, ELSO reported a survival to discharge rate of 39% for adult cardiac failure.³⁹ No meta-analyses of ECMO or randomized control trials with a mortality endpoint have been published. However, the ECMO system is likely to have the greatest potential for wider clinical use as a short-term MCS in cases such as cardiogenic shock.

TandemHeart. The TandemHeart (CardiacAssist, Inc., Pittsburgh, PA) is another percutaneously inserted device that uses a centrifugal pump. Two cannulas are inserted percutaneously with inflow from the left atrium—via a trans-septal puncture from a catheter entering from the femoral vein to the inferior vena cava to the right atrium and left atrium, and across the interatrial septum—and outflow into the femoral artery (Fig. 97-4). The pump can deliver flow rates up to 5.0 liter/min at a maximum speed of 7500 rpm. The initial clinical experience with this device for patients with high-risk PCI and post-MI cardiogenic shock has been favorable compared with

FIGURE 97-3 ■ Extracorporeal membrane oxygenation. ECMO, Extracorporeal membrane oxygenation; VA, venoarterial; VV, venovenous. FIGURE 97-4 ■ TandemHeart. (Reproduced with permission from CardiacAssist, Inc.)

FIGURE 97-5 ■ Abiomed Impella family. (Reproduced with permission from Abiomed, Inc.)

IABP.⁴⁰ Subsequent reports demonstrated the TandemHeart circulatory support led to improvement in cardiac index, decrease in pulmonary capillary wedge pressure, and recovery in end-organ function.^{41,42} However, no randomized control trial with a mortality endpoint has been conducted. The popularity of this device may be limited because of its relatively complex mode of insertion requiring trans-septal puncture.

Abiomed Impella. The Impella is an intravascular microaxial rotary pump that can be inserted across the aortic valve to provide forward blood flow from the left ventricle into the ascending aorta. The family of the Impella system includes 2.5, CP, 5.0, LD, and RP (Fig. 97-5).

The Abiomed Impella 5.0/LD—providing flow up to 5 liter/min—is inserted by a cardiac surgeon into the ascending aorta or a peripheral artery, such as the femoral or axillary artery. It is used for acute cardiogenic shock

or postcardiotomy shock. Preliminary reports demonstrated a better survival benefit with implantation of the Impella than with an IABP for patients with postcardiotomy shock.⁴³ A subsequent multicenter prospective trial demonstrated that the use of the Impella 5.0/LD in patients with postcardiotomy shock yielded favorable outcomes.⁴⁴

The Impella 2.5 is a minimally invasive cardiac assist device that is usually inserted by an interventional cardiologist percutaneously through the femoral artery up the descending aorta, across the aortic arch, down the ascending aorta, and across the aortic valve into the left ventricle. This is generally performed under either echocardiographic or fluoroscopic guidance. This device can provide flow up to 2.5 liter/min, giving partial circulatory support, and is relatively easy to implant. Clinical trials, focusing on high-risk PCI and acute MI cases,⁴⁵⁻⁴⁷ have suggested that the Impella 2.5 may provide superior hemodynamic support compared with the IABP. However, similarly to the ECMO and TandemHeart, no conclusive data with mortality as an endpoint are available for the Impella pump family.⁴⁸

The Impella CP has recently become clinically available in the United States. With a maximal flow of 3.5 liter/min, it may overcome the flow limitations of the Impella 2.5.

The Impella RP is specifically designed for RV support and is currently undergoing a clinical trial.

HeartMate Percutaneous Heart Pump. The HeartMate PHP (percutaneous heart pump; Thoratec, Pleasanton, CA) is an investigational device with a catheter-based axial flow pump (Fig. 97-6). Its collapsible elastomeric impeller and nitinol cannula allow for percutaneous insertion. The system can generate 4 to 5 liter/min of flow. It successfully completed the first-in-man phase in 2013 for adjunctive hemodynamic support during a high-risk PCI, with clinical trials planned for 2014.

FIGURE 97-6 ■ HeartMate PHP (percutaneous heart pump). In development; not approved for clinical use. (Reproduced with permission from Thoratec Corp.)

FIGURE 97-7 ■ CentriMag. (Reproduced with permission from Thoratec Corp.)

Surgical Devices for Short-Term Mechanical Support

Abiomed BVS 5000 and AB5000. The Abiomed BVS 5000 is a dual-chambered, pneumatically driven, extracorporeal pump that can be used for short-term support as a univentricular or biventricular assist device. The device is capable of flowing up to 6 liter/min. Many series have reported acceptable results with this device.^{49,50}

The Abiomed AB5000—the next-generation device after the BVS 5000—is fully automated and has a vacuum-assisted console. Advantages of this device over its predecessor include allowing patients to be more mobile and extending the duration of device support.

CentriMag. The CentriMag blood pump (Thoratec, Pleasanton, CA) is an extracorporeal centrifugal pump that is FDA approved for up to 6 hours of support time, operating without mechanical bearings or seals.⁵⁰⁻⁵² The system combines the drive, magnetic bearing, and the rotor function into a single unit (Fig. 97-7). The rotor is magnetically levitated, which enables the device to rotate

FIGURE 97-8 ■ HeartMate XVE. (Reproduced with permission from Thoratec Corp.)

without friction or wear, and eliminates heat production. This serves to minimize trauma to the blood and avoids mechanical failure. Because the rotor surface is uniformly washed, blood stagnation and turbulence in the pump are minimized. Hemolysis is reduced because the mechanical gaps in the pump are wider than 0.6 mm, reducing shear forces. The device can produce flows of up to 10 liter/min with a priming volume of 31 mL.

Implantation of a CentriMag is less technically challenging and faster than implantation of other devices. The cannulas are inserted using techniques similar to those used for routine cannulation in cardiopulmonary bypass. Another particularly useful feature of the device is the ease of adjustment of the device speed and resulting flow. Based on the patient's clinical scenario (i.e., to increase flow during periods of sepsis and decrease flow when attempting to assess weanability from the device), the speed of the device can be increased or decreased simply by pushing a button. This system can provide isolated left ventricular support as an LVAD, isolated right ventricular support as a RVAD, or biventricular support as a full-support biventricular assist device (BiVAD).^{51,52} BiVADs allow decompression of both ventricles, restore hemodynamic stability, provide enhanced peripheral perfusion, and prevent end-organ dysfunction. The CentriMag is a rescue device that can be surgically implanted in patients with acute refractory cardiogenic shock.

Long-Term Mechanical Circulatory Support

Pulsatile Devices

Thoratec HeartMate XVE. The HeartMate XVE LVAD is FDA approved for both BTT and DT (Fig. 97-8). This device has undergone several major transformations. The older version had a pump operated by a pneumatically driven mechanism and contained a large controller console. The newer-generation device is electrically vented and contains a portable console and batteries, giving patients more mobility. Furthermore, the device produces a pulsatile flow with a stroke volume of 83 mL and a maximal flow of 10 liter/min. A large landmark trial of this device has demonstrated superior outcomes compared with optimal medical management.¹

Copyright 2008 Thoratec Corporation

FIGURE 97-9 ■ Thoratec PVAD (paracorporeal biventricular assist device). (Reproduced with permission from Thoratec Corp.)

However, its long-term use is limited by the high probability of device-related complications.

Thoratec Paracorporeal Ventricular Assist Device.

The Thoratec paracorporeal VAD is a versatile device that has been used extensively for univentricular and biventricular support (Fig. 97-9). The paracorporeal placement of the pumping chamber allows the device to be implanted in patients with body surface areas of less than 1.5 m². The device consists of a polyurethane blood sac contained in a polycarbonate housing, attached to a large pneumatic console, which is used to generate a pulsatile flow with a maximal stroke volume of 65 mL. The device is capable of a flow up to 7.2 liter/min. Tilting disc mechanical valves maintain unidirectional flow. Because the device is placed paracorporeally, less dissection is required. Inflow for the LVAD is from the left atrium or LV apex, with outflow to the ascending aorta. Inflow for the RVAD is from the right atrium or right ventricle, with outflow to the pulmonary artery. The device requires systemic anticoagulation with either heparin or warfarin. With the introduction of the TLC-II portable driver, the system has become less cumbersome for patients and caregivers, improving the patients' mobility and ability to participate in rehabilitation programs.⁵³

Thoratec Intracorporeal Ventricular Assist Device.

The Thoratec intracorporeal VAD, like the paracorporeal VAD, is a versatile device that can provide isolated left, right, or biventricular support. Because it is implantable, it requires more dissection than the paracorporeal VAD. It is the first FDA-approved implantable VAD with biventricular capability for BTT and postcardiotomy shock. A multicenter trial including 39 patients supported with this device reported a success rate of 70% for BTT

and 67% for postcardiotomy recovery, which represents an improvement over historical results for the paracorporeal VAD of 69% for BTT and 48% for postcardiotomy recovery.⁵⁴

Axial Flow Pumps—Second-Generation Devices

Axial flow pumps are continuous flow pumps that operate with a propeller revolving at a set number of revolutions per minute (rpm). Advantages over pulsatile pumps include reduced noise levels and enhanced durability, the latter being attributed to fewer moving parts and contact bearings. The smaller size of these pumps also allows the device to be inserted with less dissection, because the size of the pocket is minimized and sometimes completely eliminated (Fig. 97-10).^{3,7} Disadvantages of an axial flow pump include the lack of a mechanical backup mechanism in the event of major device malfunction, hemolysis as a result of shear forces, and the potential for creating negative intraventricular pressure, with resultant device thrombosis, air embolism, or arrhythmia. Key factors in avoiding the creation of negative intraventricular pressure include preload optimization and perfect LV apical inflow cannula placement.

Several studies have evaluated the potential adverse effects of low-pulsatile continuous flow pumps on end-organ perfusion and function. On the basis of current data, adequate end-organ perfusion and function can be maintained with low-pulsatile continuous blood flow.^{55,56}

After the initial landmark trial showing a significant improvement in the quality of life and survival of patients after implantation of a continuous flow pump as compared with a pulsatile flow device (Fig. 97-11), this group of VADs has become the mainstream for BTT therapy and DT.^{3,7} Since the FDA approval of the HeartMate II device for BTT therapy in 2008 and for DT in 2010, over 98% of all LVADs implanted in the United States were continuous flow pump.⁶

Thoratec HeartMate II. The Thoratec HeartMate II VAD is an axial flow rotary pump constructed of titanium (Fig. 97-12), which can generate flows up to 10 liter/min operating at pump speeds of 6000 to 15,000 rpm. Inflow is via the LV apex, and outflow is via the ascending aorta. The axial flow design eliminates the need for a blood-pumping chamber and volume compensation necessary for volume-displacement LVADs. The pump housing is implanted in the small preperitoneal space and requires only a small pocket. A small percutaneous driveline exits the skin in the right or left upper abdomen. This feature makes the device more suitable for implantation in patients with a smaller body size. Theoretical benefits over previous series of VAD system include a reduced risk of infection, greater patient comfort and quality of life, and greater device durability. Furthermore, it is substantially smaller than the HeartMate XVE and requires a less invasive operative approach. A randomized control trial demonstrated the superiority of the HeartMate II compared with the HeartMate XVE in terms of survival, quality of life, and durability.³ The HeartMate II is approved by the FDA for both BTT therapy and DT.

FIGURE 97-10 ■ **A**, Pulsatile flow device. **B**, Continuous flow device. *LVAD*, left ventricular assist device. (Reproduced with permission from Slaughter MS, Rogers JG, Milano CA, et al: Advanced heart failure treated with continuous flow left ventricular assist device. *New Engl J Med* 361(23):2241–2251, 2009.)

The accumulating clinical experience suggests that the pump is associated with a notable improvement in survival. The original HeartMate II BTT trial demonstrated a 1-year overall survival rate of 68%, which has improved to 85% according to more recent data.⁷ In the HeartMate II DT trial, the 2-year survival rate improved from 58% in the early era to 63% in the later era.⁵⁷

Jarvik 2000. The Jarvik 2000 (Jarvik Heart, Inc., New York, NY) is an electromagnetically actuated pump constructed of titanium, measuring 2.5 cm in diameter and weighing 90 g (Fig. 97-13), with a displacement of approximately 30 mL. The titanium impeller blades are

held in place by ceramic bearings. The impeller rotates at speeds of 8000 to 12,000 rpm and can generate a flow of up to 7 liter/min. A unique feature of this device is that the pumping chamber is implanted in the left ventricle. The outflow graft is anastomosed to the descending thoracic aorta. Surgical implantation of the device is typically accomplished through a left thoracotomy.⁵⁸ The pump speed can be adjusted by an external controller dial ranging from 1 to 5. The speed setting of 1 is the slowest, driving the impeller at 8000 rpm and producing a blood flow of 1 to 2 liter/min, whereas the speed setting of 5 is the fastest, driving the impeller at 12,000 rpm and producing a blood flow of 5 to 7 liter/min.⁵⁹

The multiple versions of the Jarvik 2000 device can be differentiated by their energy source. The percutaneous model has a single driveline that exits through the patient's anterior abdominal wall. One version contains skull-mounted pedestals used with cochlear implants: a titanium pedestal is screwed into the skull with a transcutaneous connector that attaches to the power cord. The behind-the-ear cable system may have significant quality-of-life advantages and reduced risk of infection

FIGURE 97-11 ■ Survival after continuous versus pulsatile flow left ventricular assist device (LVAD) implant. (Reproduced with permission from Slaughter MS, Rogers JG, Milano CA, et al: Advanced heart failure treated with continuous flow left ventricular assist device. *New Engl J Med* 361(23):2241–2251, 2009.)

compared with the abdominal cables. Furthermore, it enables patients to shower and bathe normally and even go swimming. This system is currently under trial for DT.^{59,60}

MicroMed DeBakey. The MicroMed DeBakey VAD (MicroMed Cardiovascular, Inc., Houston, TX) was developed as a collaborative effort between the Baylor College of Medicine and National Aeronautics and Space Administration engineers. The pump unit for the MicroMed DeBakey VAD is made of titanium, weighs 95 g, and measures only 1.2 inches in diameter and 3 inches in length. The impeller is capable of generating flows up to 10 liter/min. A relatively high number of reports have described stroke and microemboli formation with this device.^{61,62} The child version is approved by the FDA for BTT use in children aged 5 to 16 years.

Newer (Third-) Generation Pumps and Future Devices

Newer-generation devices, so-called third-generation devices, have been designed to address several shortcomings of second-generation axial flow pumps, such as thromboembolic complications and limited device durability. Many of these devices operate on the basis of magnetic levitation technology, in which the rotating propeller is magnetically suspended in a column of blood, obviating the need for contact-bearing moving parts and providing the theoretical benefit of enhanced durability. Continuous flow pumps are generally smaller, can be inserted with only a small device pocket or no pocket at all, are less traumatic, and may have a decreased risk for

associated infection. Some have been designed to be completely implantable with a transcutaneous energy transfer system. Along with smaller control consoles, these devices allow patients to be readily discharged from the hospital and increase their ability to ambulate. These devices will probably be associated with a significant improvement in quality of life for patients.

HeartWare HVAD. The HeartWare HVAD (HeartWare International, Inc., Framingham, MA) is a centrif-

gal pump with no mechanical bearings (Fig. 97-14), weighing 145 g, with a displaced stroke volume of 45 mL and a flow of up to 10 liter/min at 2000 to 3000 rpm. The inflow cannula is integrated into the left ventricle. The device is implanted in the pericardial space without the need for an abdominal incision. This miniaturized device may be used as a biventricular assist system as well as an LVAD.⁶³ A single, flexible driveline measuring 4.2 mm in diameter exits the anterior abdomen. The device has been tested in several centers throughout

Europe with good results.^{64,65} A clinical trial of BTT demonstrated noninferior 180-day survival to contemporary LVAD registry controls in the United States.⁶⁶ In the study, 127 out of 140 patients (91%) either survived for at least 180 days on the pump or received a heart transplant within that time. The HeartWare LVAD is approved by the FDA for BTT therapy.

The HeartWare MVAD is an investigational device with a continuous axial flow pump, approximately one-third the size of the HVAD.

DuraHeart. The Terumo DuraHeart LVAD (Terumo Heart, Inc., Ann Arbor, MI) uses magnetic levitation technology.⁶⁷ The device can provide a flow of 2 to 8 liter/min at 1200 to 2400 rpm. In case of magnetic failure, the device can levitate the Impella hydrolytically. The pump weighs 540 g and has a diameter of 72 mm and a height of 45 mm. Favorable clinical outcomes as a BTT therapy have been reported in studies conducted in Europe and Japan.^{68,69}

Thoratec HeartMate III. The Thoratec HeartMate III device is also a magnetically suspended centrifugal pump, powered by a magnetically levitated centrifugal impeller (Fig. 97-15). The device can provide a flow of 10 liter/min. This device has the ability to produce a pulsatile flow and has a large gap that may significantly reduce shear stress.⁷⁰ This device is not currently being tested in any clinical trials.

Synergy. The Synergy (HeartWare International, Inc., Framingham, MA) device is a partial-support LVAD that can be placed intravascularly (Fig. 97-16). An inflow cannula is placed through the subclavian vein, into the right atrium, and across the interatrial septum into the left atrium. Outflow is to the subclavian artery. Data from a European trial showed that the partial-support LVAD can provide improvements in hemodynamics and a reduction of heart failure symptoms.⁷¹

Total Artificial Heart

MCS options for patients requiring long-term biventricular support remain limited. TAH currently represents one long-term treatment option for patients requiring biventricular support.⁷² Others include paracorporeal BiVAD and implantable BiVAD.^{53,54} Thus,

despite the enthusiasm of continuous flow pumps, pulsatile technology still has an important role in the treatment of biventricular failure. BiVAD provides biventricular support for the failing native heart, which is left intact. TAH completely replaces the failed ventricles and the four native valves in the orthotopic position. By replacing the failing heart, the TAH can eliminate the native heart complications such as valve dysfunction and arrhythmias.

The TAH is currently approved by the FDA only for BTT. The use of TAH is indicated in transplant candidates at risk of imminent death from nonreversible biventricular failure. Contraindications include transplant ineligibility, absence of biventricular failure, inability to have anticoagulation, and small thoracic cavity size.⁷² According to INTERMACS data, only 2% of current MCS implants are TAH.⁶ A recent large report of 101 patients receiving TAH demonstrated survival to transplantation rate of 68% and 1-year overall survival rate of 77% after transplant.⁷³ Recent retrospective data from Europe showed no difference in survival rate while on support and after transplant between TAH, paracorporeal BiVADs, and implantable BiVADs.⁷⁴ No randomized prospective clinical trials have compared TAH with BiVAD.

SynCardia

The SynCardia TAH (SynCardia Systems, Inc., Tucson, AZ) system is a pneumatic, pulsatile, biventricular device that completely replaces a patient's native ventricles and all valves, while pumping blood to both the pulmonary and the systemic circulation orthotopically (Fig. 97-17). The system consists of the implantable SynCardia TAH and an external console connected via drivelines. It weighs 160 g and displaces 400 mL of volume. It is lined

FIGURE 97-15 ■ HeartMate III. In development; not approved for clinical use. (Reproduced with permission from Thoratec Corp.)

FIGURE 97-16 ■ Synergy. (Reproduced with permission from HeartWare, Inc.)

FIGURE 97-17 ■ SynCardia total artificial heart. (Reproduced with permission from SynCardia Systems, Inc.)

with polyurethane and has a four-layer, pneumatically driven diaphragm. Four mechanical Hall valves (Medtronic, Inc.) (two 27-mm inflow, two 25-mm outflow) are mounted on the housing. The diaphragm within the pump is actuated by movement of air from an external console. At maximal stroke volume (70 mL), it delivers a cardiac output of more than 9 liter/min. The artificial ventricles are connected via atrial inflow connectors to the native left and right atrium and to the native aorta and pulmonary artery by the outflow cannulas. The major drawbacks are the complexity of the implant procedure, relatively large device size (body surface area > 1.7 m² and thoracic diameter of at least 10 cm are required), and higher noise level compared with continuous flow pumps. This device is approved by the FDA for BTT therapy. A landmark trial including 81 patients who received SynCardia TAH demonstrated survival to transplantation rate of 79%, 1-year overall survival of 70%, and 1- and 5-year survival rates of 86% and 64% after transplantation, respectively.⁷² The most common adverse events were infection and bleeding.

DEVICE SELECTION

A wide spectrum of MCS devices is available. Important factors that should be considered when selecting a device include the expected duration of support (short- versus long-term support); whether right, left, or biventricular support is required; the patient's neurologic status and overall prognosis; and whether the intent is to bridge the patient to recovery or to transplant, or if the device is to serve as DT. Other important patient-specific factors include the patient's body habitus, blood type, transplant candidacy, and contraindications to anticoagulation. Surgeon preference, level of familiarity, and device availability may also play a role in deciding which device to implant. Moreover, these issues should be raised during multidisciplinary team discussions with experienced surgeons and cardiologists.

INDICATIONS FOR MECHANICAL CIRCULATORY SUPPORT

Major indications for MCS include acute cardiogenic shock after acute MI, postcardiotomy cardiogenic shock, myocarditis, refractory ventricular arrhythmias, acute on

chronic heart failure, and chronic heart failure. Patients can be roughly divided into the following two categories depending on the trajectory of heart failure progression and overall clinical status: (1) patients with acute cardiogenic shock, or (2) patients with chronic advanced heart failure.

Patients in Acute Cardiogenic Shock

Implantation of durable LVADs is associated with poor outcomes in patients with acute cardiogenic shock (INTERMACS level 1) after an acute MI, myocarditis, acute on chronic heart failure, or after cardiectomy.⁶ Generally, transplant eligibility is uncertain in patients with a combination of end-organ failure, uncertain neurologic status, and uncertain social support. Furthermore, the recent IABP-SHOCK II trial suggested that IABP confers no benefit in cardiogenic shock associated with acute MI.^{75,76} Therefore, there is clearly a role for short-term MCS in this population to provide BTD, BTT, or recovery (Fig. 97-18). The current options include the VA-ECMO, Impella, TandemHeart, and CentriMag. Each of these devices seems to be safe, effective, and reliable.^{38-42,44,50-52} They can provide optimal flow to this subset of very-high-risk patients in cardiogenic shock whose predicted mortality rate is almost 100% without mechanical support. In our program, the VA-ECMO or CentriMag BiVAD is preferably used. For patients with unclear neurologic status, profound shock, and severe coagulopathy, the less invasive VA-ECMO is selected. After resuscitation with these short-term devices, the patient's neurologic status, end-organ function, and myocardial function can be evaluated appropriately. Depending on the results, the short-term MCS device is explanted as a transition to each definitive goal (BTD). Ninety patients received either the ECMO or the CentriMag BiVAD through this algorithm for cardiogenic shock. An exchange with an implantable VAD was required in 26% of patients. Other destinations included myocardial recovery in 18% and heart transplantation in 11%. The survival to hospital discharge rate was 49%.⁷⁷

Cardiogenic Shock after Acute Myocardial Infarction

Approximately 6% to 7% of all MI patients develop cardiogenic shock as a complication, with most of these being ST-elevation MIs.⁷⁸ When cardiogenic shock

FIGURE 97-18 ■ Patient and device selection flow chart. *BTD*, Bridge to decision; *BTT*, bridge to transplant; *DT*, destination therapy; *MCS*, mechanical circulatory support; *OHT*, orthotopic heart transplantation.

complicates an acute MI, the reported associated mortality rate has traditionally been 85% to 90%.⁷⁹ For patients with refractory cardiogenic shock despite maximal pharmacologic support, the mortality rate approaches 100%.⁸⁰ Moreover, a recent large prospective randomized trial demonstrated that additional IABP treatment did not result in a significant reduction in 30-day mortality rate compared with medical therapy alone.^{75,76} Implantation of a MCS device to provide adequate circulatory support may be the only viable option for survival in these cases. By providing adequate circulatory support, MCS can reverse hypotension while maintaining vital organ perfusion and adequate coronary perfusion pressures.^{42,46-48} The goal of MCS in patients with cardiogenic shock after an acute MI is to bridge the patient to a second procedure, which includes PCI, CABG, CABG plus valve, implantation of a long-term durable LVAD, and explantation of the short-term MCS devices after myocardial recovery.

Cardiogenic Shock after Cardiotomy

Patients in cardiogenic shock after cardiotomy are also best treated with a short-term MCS device. Like the goal of mechanical support in patients after an acute MI, the goal of mechanical support in patients with cardiogenic shock after cardiotomy—irrespective of which mechanical device is used—is to bridge the patient to a second procedure, which includes implantation of a long-term durable LVAD, as well as explantation of the short-term MCS after myocardial recovery.^{44,81,82}

Myocarditis

Acute heart failure and cardiogenic shock from myocarditis are seen typically in a younger patient population. Because the probability of recovery is relatively high in these patients, they should receive a short-term MCS device, such as the ECMO or CentriMag.⁸³ In general, our preference is to implant a biventricular device in

these patients. After normalization of end-organ perfusion and function, myocardial function and recovery are assessed.

Refractory Ventricular Arrhythmias

The subgroup of patients with refractory arrhythmias is heterogeneous. Some do not have significantly reduced cardiac function, whereas others have severely depressed ejection fractions.^{24,25,84} Pharmacologic therapy, such as amiodarone, lidocaine, and beta blockers, failed to control their arrhythmias. Among the patients with reduced LV function, RV function can be either preserved or reduced. These patients can be candidates for both short-term and long-term MCS.

Patients with Chronic Advanced Heart Failure

A progression to chronic heart failure is characteristic of the largest subgroup of patients who receive long-term, durable LVADs. There are two definitive arms depending on transplant eligibility (BTT or DT).^{1,6-8} However, the initial management plan can change over time. For example, comorbidities may improve in a DT patient who was previously ineligible for transplant, making the patient transplant-eligible after LVAD support. Alternatively, a BTT patient may become transplant-ineligible because of device-related complications or progression of comorbidities. Additionally, the INTERMACS registry data demonstrated that 42% of the durable LVAD implants were intended as a BTC.⁶ Thus, in a dynamic clinical situation, it is often difficult to decide between BTT and DT.

Patients Who Are Eligible for Heart Transplantation

Heart transplantation is the optimal treatment for patients with a history of chronic congestive heart failure who

may have additional chronic deterioration or an acute exacerbation. However, the constant shortage of available donors has resulted in an increasing number of patients with longer waiting times on the transplantation lists. The use of a long-term durable LVAD as a BTT has become common in patients who would otherwise not survive or who would develop progressive end-organ dysfunction before an organ becomes available.^{7,31} Dependence on intravenous inotropes (INTERMACS profile level 2 or 3) is traditionally considered the threshold that accelerates consideration of durable VAD therapies in these patients. The BTT strategy is especially reasonable in patients listed for transplant who are expected to have an extended waiting time because of their blood type, large body size, or high degree of allosensitization.

Since the FDA approved the HeartMate II, placement of a continuous flow LVAD such as the HeartMate II or HeartWare has been the mainstream circulatory support therapy for these patients. They are often discharged from the hospital after their VAD is implanted and return at a later date for a transplant.^{7,66} Contemporary, continuous flow, durable LVADs have favorable waiting list outcomes, unless a serious LVAD-related complication occurs.⁸⁵ In addition, the data from the UNOS registry demonstrated that posttransplant graft survival after a bridge with continuous flow durable LVADs was similar to that in patients bridged with inotropes or pulsatile flow LVADs.⁸⁶

Patients Who Are Not Eligible for Heart Transplantation

The REMATCH trial, which randomized 129 non-transplant candidates to optimal medical therapy or mechanical support, demonstrated a 48% reduction in

the risk of death from any cause in the LVAD group compared with the group of patients treated with optimal medical therapy.¹ Based on this result, the FDA approved the use of an LVAD (HeartMate XVE) as a lifelong support therapy (DT). Mortality rate increases to an almost prohibitive value with the onset of end-organ failure—such as renal failure—and in the presence of active infection. In a study of 280 patients who underwent HeartMate XVE LVAD implantation as DT in the post-REMATCH era, the most important determinants of in-hospital mortality were poor nutrition, hematologic abnormalities, markers of end-organ or RV dysfunction, and lack of inotropic support.²⁶ Current requirements for DT are patients with NYHA class IV end-stage ventricular heart failure who are not candidates for heart transplant and who meet all the following conditions: (1) have failed to respond to optimal medical management (including beta blockers and ACE inhibitors, if tolerated) for at least 45 of the last 60 days, or have been balloon pump dependent for 7 days, or IV inotrope dependent for 14 days; (2) have a left ventricular ejection fraction less than 25%; and (3) have demonstrated functional limitation with a peak oxygen consumption of up to 14 mL/kg/min unless balloon pump or inotrope dependent, or physically unable to perform the test.

Currently, the FDA-approved continuous flow device for DT is the HeartMate II. Since the approval of HeartMate II for DT in 2010, the number of LVADs implanted for lifelong support in transplant-ineligible patients has increased up to 10-fold.⁶ The evolution from pulsatile to continuous flow technology has dramatically improved survival in these patients. A large body of data from the INTERMACS registry demonstrated a 1-year survival rate of 75% (Fig. 97-19).⁸⁷ A subset of their population with no cancer, not in cardiogenic shock, and blood urea

FIGURE 97-19 ■ Survival after left ventricular assist device (LVAD) implant as a destination therapy. (Reproduced with permission from Kirklin JK, Naftel DC, Pagani FD, et al: Long-term mechanical circulatory support [destination therapy]: on track to compete with heart transplantation? *J Thorac Cardiovasc Surg* 144(3):584–603, 2012.)

nitrogen less than 50 mg/dL experienced a 2-year survival rate of 80% or more, which is competitive with heart transplantation.

Given the improvements in technology, as well as in patient selection and care over the past decade, there is a movement to use LVAD therapy in patients who are less ill than those currently eligible for DT. The NHLBI has sponsored the Randomized Evaluation of the VAD intervention before the Inotropic Therapy (REVIVE-IT) trial to test the LVAD therapy in advanced heart failure patients with significant functional impairment who are ineligible for transplant but who have not yet manifested serious consequences of end-stage heart failure, such as end-organ dysfunction, immobility, or cardiac cachexia.⁸⁸

SURGICAL TECHNIQUE USED FOR DURABLE LEFT VENTRICULAR ASSIST DEVICE IMPLANTATION

The technique used for durable LVAD implantation varies depending on the institution and the surgeon. However, the common steps in the operation can be summarized as follows: (1) skin incision; (2) creation of a preperitoneal pocket, if required; (3) mediastinal exposure; (4) cannulation of the aorta and venous system; (5) cardiopulmonary bypass commencement; (6) coring of the LV, placing core sutures on the LV, inserting the inflow core into the LV apex; (7) outflow graft anastomosis to the ascending aorta; (8) de-airing of the device; (9) weaning off cardiopulmonary bypass, actuating LVAD; (10) hemostasis establishment; (11) closing sternotomy.

A vertical midline incision is made beginning just below the sternal notch with variable extension below the xyphoid, depending on the type of device being implanted and the required pocket size based on the device used. A sternotomy is made. A pocket of an appropriate size is created in the preperitoneal space in the upper abdomen. Alternatively, the LVAD pocket can be created between the posterior rectus sheath and the muscle. Careful attention is given to hemostasis during this process. If applicable, a model of the device is used to confirm the appropriate size of the pocket. The driveline is tunneled, exiting the patient via the right upper quadrant. The device is then placed in the preperitoneal pocket.

The patient is fully heparinized. The distal ascending aorta is cannulated at the level of the pericardial reflection. The right atrium is cannulated—unless a tricuspid valve repair or closure of an atrial septal defect is planned, in which case the patient is bicavally cannulated with umbilical tapes and snares placed around the superior and inferior vena cava cannulas.

Cardiopulmonary bypass is then commenced, maintaining normothermia. The LV is decompressed by placing a vent through a stab wound at the LV apex. The LV apex is then cored. Care must be taken when coring to avoid deviation into the septum or the lateral wall. Any prominent trabeculation or thrombus that may impede inflow into the LVAD inflow cannula is excised. Full-thickness 2-0 Tevdek pledget sutures (Genzyme, Fall River, MA) are placed in a horizontal mattress fashion

around the circumference of the LV core. For the fragile myocardium, this suture line is reinforced with a strip of Teflon felt. The sutures are placed through the sewing ring of the inflow cuff, the sewing ring is seated, and the sutures are tied. The cuff is then inserted into the inflow cannula and secured with multiple ties.

The ascending aorta is clamped with a side-biting, partial-occluding clamp. An aortotomy is made, followed by the outflow graft anastomosis using 4-0 Prolene pledget sutures, which involves placement of two mattress sutures buttressed with pledgets in the heel and toe of the graft and corresponding aorta, followed by parachuting of the graft down onto the aorta. BioGlue (CryoLife, Inc., Kennesaw, GA) is applied to the anastomosis just before the clamp is released. The anastomosis is then inspected for bleeding. The outflow graft is clamped.

The de-airing process is then commenced by allowing the heart to fill under mechanical ventilation. The device is de-aired through the outflow housing. The outflow graft is connected to the outflow housing, and a de-airing hole is made in the outflow graft. The cross-clamp is kept on the outflow graft.

With the HeartMate II, the device is started only after the de-airing is completed and the patient is off cardiopulmonary bypass. The device is started at 6000 rpm, the cross-clamp is released, and the device's speed is gradually increased to an adequate rpm level to avoid oversucking of the LV. Throughout this process, the de-airing hole in the outflow graft is kept open.

Chest tubes are inserted. A Gore-Tex pericardial membrane (Gore Medical Products, Flagstaff, AZ) or a CorMatrix (CorMatrix Cardiovascular, Inc., Alpharetta, GA) is sutured to the pericardial edges to minimize reentry injury at reoperation. The sternum is closed in the standard fashion. The abdominal portion of the incision is closed with interrupted sutures, with careful attention to obtain adequate purchase of the fascia and avoid wound dehiscence. The superficial soft tissue and skin are closed in the standard fashion.

In the event of a diffuse coagulopathy with excessive bleeding, the mediastinum is packed with long rolls of gauze and a patch is placed on the skin. The patient is brought back to the operating room after adequate resuscitation and when the coagulopathy has resolved, which generally occurs 24 hours after the initial surgery.

Concomitant Valve Surgery

Preexisting valve pathology is common in patients with heart failure. Patients frequently require concurrent valve procedures at the time of LVAD placement. Patients with mild or more severe aortic insufficiency (AI) should have their native aortic valve repaired or oversewn at the time of VAD implantation. Most cases of AI can be repaired by approximating the raphe of each leaflet.^{89,90} Any patient with a mechanical valve in the aortic position should have the aortic valve oversewn with a patch or replaced with a tissue valve to prevent thromboembolism. Treatment of significant mitral regurgitation (MR) is controversial. The cause of most cases of MR in patients with advanced heart failure is annular enlargement secondary to LV dilation. In general, once the LV is unloaded with the

LVAD, MR will likely improve. However, a recent study demonstrated that approximately one third of the patients continued to have significant MR after LVAD insertion.⁹¹ In addition, concomitant mitral valve repair may result in a greater decrement in pulmonary vascular resistance.⁹² Currently, we prefer to address significant MR. Severe mitral stenosis needs to be repaired at the time of VAD implantation if it significantly interferes with inflow to the device. Moderate to severe tricuspid regurgitation should be considered for repair or replacement to optimize RV function.^{93,94} This is especially important for patients with pulmonary hypertension. Tricuspid valve repair can be performed with annuloplasty repair. If the valve lesions cannot be repaired, a tissue valve is preferred because it has a lower risk of thromboembolism than does a mechanical valve.

Patients who require valve procedures are sicker and have a higher early mortality rate. Furthermore, RV dysfunction is increased in these patients.⁹⁵

Other Concomitant Procedure

Patients with an atrial septal defect or a patent foramen ovale should have these lesions corrected at the time of VAD implantation using standard techniques. Failure to correct these lesions may result in severe hypoxia as a result of right-to-left shunting after the left ventricle is unloaded. Furthermore, any intracardiac thrombus identified in the left atrium or ventricle should be removed before LVAD implantation.

POSTOPERATIVE MANAGEMENT AFTER DURABLE LEFT VENTRICULAR ASSIST DEVICE IMPLANTATION

Early Postoperative Management

Antibiotics are administered preoperatively as prophylaxis for infection and are continued for at least 24 hours after LVAD implantation.

Major effects of a continuous flow LVAD on hemodynamics include increased diastolic pressure and flow. Because a continuous flow pump generates blood flow throughout the entire cardiac cycle, the pulse pressure is greatly reduced. The pulse pressure is influenced by LV contractility, preload, afterload, and pump speed (rpm). An increase in pump speed leads to rising of the diastolic pressure and reduced pulsatility—making it often difficult to palpate the patient's pulse. An arterial catheter is mandatory to monitor blood pressure in the early postoperative period. The mean arterial blood pressure should be maintained between 70 and 80 mm Hg with pressors, because the amount of blood flow through a continuous flow pump is greatly affected by afterload. Vasodilatory hypotension is treated with norepinephrine and arginine vasopressin.⁹⁶

Optimization of RV function is crucial for patients receiving isolated LVAD. RV failure should be aggressively treated with milrinone, dobutamine, epinephrine, and nitric oxide.^{12,13,97} If the optimization of RV function

cannot be achieved by pharmacologic treatments, RVAD support should be considered.

Ventricular and atrial arrhythmias are managed with standard antiarrhythmic agents, such as amiodarone and lidocaine.

Late Postoperative Management

Late postoperative management focuses on encouraging ambulation and rehabilitation as well as patient education about the care and maintenance of the device. After discharge, patients are followed at the outpatient LVAD clinic weekly for the first month after discharge from the hospital and less frequently thereafter. Although continuous flow technology has dramatically improved survival and quality of life, readmission because of bleeding, cardiac difficulties (heart failure and arrhythmia), infections, and thrombosis is common within the first 6 months after discharge.⁹⁸ Comprehensive care from a multidisciplinary medical team, including the patient and caregivers, is mandatory for successful long-term LVAD support.

Anticoagulation

The HeartMate I XVE does not require anticoagulation with heparin or warfarin. In contrast, contemporary continuous flow LVADs such as HeartMate II and HVAD all require anticoagulation with warfarin, as well as antiplatelet therapy with aspirin—and occasionally Persantine—to prevent thromboembolic complications. Intravenous heparin is generally used until the INR reaches target range in the postoperative period. The decision as to when to start anticoagulation and antiplatelet therapies, as well as the dosage, is individualized for each patient based on the device type, risk of thromboembolism, chest tube output, coagulation profile, and treatment plan for the patient.

COMPLICATIONS

Postoperative Bleeding

Bleeding after VAD insertion can be excessive and may result from surgical causes or a diffuse coagulopathy. Significant bleeding can contribute to RV failure, infection, and numerous adverse effects related to multiple blood transfusions. Coagulopathy can result from alterations in the hemostatic system, including dilutional thrombocytopenia and exposure to long-acting antiplatelet or antithrombotic agents. For bleeding caused by a diffuse coagulopathy, platelets, fresh-frozen plasma, or cryoprecipitate may be administered. The decision as to whether to administer these products is based on the profile of INR, partial thromboplastin time, and fibrinogen. Patients with coagulopathy are often hypothermic and should be warmed with heating blankets. A bleeding patient with a rising central venous pressure, downward-trending VAD flows, increasing pressor requirements, and decreasing urine output should be presumed to be experiencing tamponade and should be taken to the operating room immediately for reexploration.

Gastrointestinal Bleeding and Epistaxis

Gastrointestinal (GI) tract bleeding and epistaxis have emerged as major sources of morbidity in patients with continuous flow LVADs.⁹⁹ The bleeding event rate after HeartMate II implantation was 0.67 events per patient-year.¹⁰⁰ Possible mechanisms associated with obligate device anticoagulation include acquired von Willebrand disease, GI tract arteriovenous malformations associated with reduced pulsatility, and impaired platelet aggregation.⁹⁹ The management of bleeding issues is inextricably linked to the risk of thromboembolic events. Considering the individual risks and benefits, careful reduction of anticoagulation and antiplatelet therapy is required for recurrent events.

Infection

Infection, one of the most common complications in LVAD patients, can manifest as a driveline, pocket, blood, or device endocarditis.¹⁰¹ Sepsis occurs in 17% to 28% and driveline infection occurs in 14% to 27% of patients receiving contemporary continuous flow LVADs.^{3-7,57,66} It is important to prophylactically begin antibiotics preoperatively, as previously described, as well as to treat infections aggressively with antibiotics when they do occur. More aggressive treatments including surgical drainage, wound vacuum-assisted closure therapy, and pump exchange may be necessary. The only way to definitively eradicate device endocarditis is to explant the device. Infection is generally not a contraindication to heart transplantation.

Multisystem Organ Failure

Despite effective restoration of adequate cardiac output for tissue perfusion, some patients progress to develop multisystem organ failure—which is related to the preoperative severity of organ dysfunction. Multisystem organ failure often results from a cascade of events, such as bleeding, sepsis, RV failure, and other events.

Thromboembolism

Thromboembolic complications are a major concern in LVAD patients because of the blood-device interface. Thromboembolic events with continuous flow LVADs have been reported to occur in 5% to 8% of cases.^{3-7,57,66} The key factors associated with development of stroke after LVAD implantation are likely to include a previous history of stroke, persistent malnutrition and inflammation, increased severity of heart failure, and postoperative LVAD infections.¹⁰² To avoid conversion to hemorrhagic stroke, anticoagulation and antiplatelet therapies may need to be discontinued.

Right Ventricular Failure

Adequate RV function is essential to achieve sufficient LVAD flow. Significant RV failure is associated with poor outcomes in LVAD recipients. The incidence of RV failure after continuous flow LVAD implantation is

approximately 20%.¹⁰⁻¹³ The proposed underlying mechanisms include intrinsic myocardial dysfunction and insufficient RV afterload reduction.¹⁰⁻¹³ It is important to keep in mind numerous other potential complications after LVAD surgery such as renal failure, infection, and bleeding, which might predispose patients to RV failure. Additionally, patients with a continuous flow pump can develop RV failure from a significant leftward septal shift and distortion of RV geometry caused by LV oversucking. It is therefore critical to avoid setting an excessive pump speed in continuous flow LVAD recipients. Postoperative echocardiography should be performed routinely to monitor RV function, and pump speed should be adjusted to adequate speed levels (rpm).

Signs of RV failure include an elevated central venous pressure (>15 mm Hg), marginal VAD flows of up to 2.2 liter/min/m², low mixed venous oxygen saturation, and decreased urine output. RV failure treatment involves aggressive diuresis and starting or increasing milrinone and/or dobutamine as well as nitric oxide in some cases.⁹¹ When RV failure is refractory to medical management, timely insertion of a RVAD is mandatory before end-organ dysfunction progresses.^{12-14,103}

Arrhythmia

Cardiac arrhythmia, especially ventricular arrhythmia, is also a common issue in the early and late postoperative periods. Although such arrhythmia may not be lethal in the presence of LVAD, it could put patients at risk of RV failure. Adjustment of pump speed under echocardiography may be necessary to evaluate excessive LV unloading or contact between the inflow cannula and LV wall. In addition to implantable cardioverter-defibrillator therapy, interventions aimed at minimizing the risk of recurrent arrhythmias (e.g., antiarrhythmic medication use and catheter ablation) may also be considered.¹⁰⁴

Aortic Insufficiency

The development of de novo AI during a continuous flow LVAD support has been reported. After receiving continuous flow LVAD support for 3 years, 38% of patients are expected to develop at least moderate AI.¹⁰⁵ Significant AI can cause the recycling of blood flow from the LVAD outflow graft into the LV, resulting in decreased forward cardiac output, inadequate ventricular unloading, and increased pump work. This may lead to clinical decompensation requiring surgical correction. Because the non-opening of the aortic valve during continuous flow LVAD support is strongly associated with de novo AI development, optimization of pump speed under echocardiography may be necessary to maintain some pulsatility with intermittent aortic valve opening.¹⁰⁵

Device Malfunction

The severity of a device malfunction varies from minor to fatal. With improvement in device design and engineering, the overall incidence of serious device malfunctions has decreased significantly over time.¹⁰⁶ However, device replacement related to device failure is still

inevitable in some patients. Of the 1128 patients implanted with the HeartMate II, serious device failure requiring pump replacement occurred in 71 (6.4%) patients for the following reasons: percutaneous lead damage (36 events, 3.0%), device thrombosis (25 events, 2.1%), infection (7 events, 0.6%), and miscellaneous other (11 events, 0.9%).¹⁰⁷ Most recently, an unexpected abrupt increase in the device thrombosis rate with the HeartMate II has been reported.¹⁰⁸ In an analysis of 382 patients who underwent implantation of the HeartWare HVAD, pump thrombosis occurred in 8.1% of the cohort.¹⁰⁹ Device thrombosis is caused by various mechanical or nonmechanical factors.¹¹⁰ Close monitoring of lactate dehydrogenase levels and echo-guided ramp studies are useful for early detection of device thrombosis.^{110,111} Pump exchange can be safely performed through a subcostal approach.¹¹²

SUMMARY

MCS represents the standard of care for patients with advanced heart failure from various causes. In addition, MCS may be used as a BTT or a DT and may be the only option for survival in patients with acute cardiogenic shock that is refractory to maximal medical therapy. Tremendous progress has been made over the past 10 years with respect to the evolution of devices, patient selection, surgical techniques, and postoperative management of patients. The limitations of current devices have stimulated research and innovation in an attempt to reduce device size, minimize the invasiveness of the surgical approach, increase device durability, decrease infection, reduce associated thromboembolic complications, and enhance the quality of life of patients with MCS. The outcomes can be expected to improve as the technology continues to evolve.

CHAPTER OUTLINE

HISTORICAL BACKGROUND

INDICATIONS AND EVALUATION FOR HEART TRANSPLANTATION

Recipient Selection
Allosensitization in the Heart Transplant Recipient
Recipient Management after Listing

ORGAN PROCUREMENT AND PRESERVATION

Donor Selection
Donor Management
Organ Allocation
Donor and Recipient Matching
Donor Operative Technique
Organ Preservation

RECIPIENT OPERATIVE TECHNIQUE

Orthotopic Standard Technique
Orthotopic Bicaval Technique
Orthotopic Total Technique
Heterotopic Technique

RECIPIENT POSTOPERATIVE MANAGEMENT

Clinical Management in the Early Postoperative Period
Maintenance Immunosuppression

COMPLICATIONS

Hyperacute Rejection
Acute Rejection
Acute Cellular Rejection
Treatment of Acute Cellular Rejection
Antibody-Mediated Rejection
Treatment of Antibody-Mediated Rejection
Infection
Cardiac Allograft Vasculopathy
Neoplasm

LONG-TERM RESULTS IN HEART TRANSPLANTATION

SUMMARY

In the span of 5 decades, cardiac transplantation has progressed from an experimental dream to a treatment reality for patients with heart failure.¹ According to the 2013 Registry of the International Society for Heart and Lung Transplantation, 4096 transplants were performed in 2011. The registry captures an estimated 66% of all transplants. Short- and long-term results improved until 2006, after which they remained stable.² Consequently, heart transplantation has continued to be the gold standard for surgical treatment of heart failure. With a rising prevalence of heart failure, it is estimated that more than 25,000 patients annually could benefit from cardiac transplantation.³ Despite this, the limiting factor continues to be the donor organ supply. Therefore, more importance has been placed on expanding the donor pool while developing alternative medical and surgical therapies. These therapies are meant to either bridge the heart failure patient to heart transplantation or serve as a destination therapy.

This chapter reviews the current practice of cardiac transplantation. Importance is placed on donor and recipient selection, recipient management, identifying and managing complications, and long-term results.

HISTORICAL BACKGROUND

The success of heart transplantation can be traced to the 1950s to 1960s, when pioneering achievements in the laboratory eventually translated to clinical usefulness. The earliest attempts at experimental heart transplantation involved heterotopically implanting hearts in animals through vessels in the neck or abdomen. In 1905, Alexis Carrel and Charles Guthrie⁴ revealed that heterotopically transplanted hearts resume spontaneous contraction for several hours. Continued inquiry into the physiologic basis of heart transplantation generated further advancement and interest. This included the important work of Vladimir Demikhov,⁵ in which he implanted both heterotopic and orthotopic hearts in the thorax. The advent of hypothermia and mechanical pump oxygenators in the 1950s made orthotopic heart transplantation (OHT) a stronger possibility. In the 1960s at Stanford University, Richard Lower and Norman Shumway⁶ continuously refined the technique of experimental OHT. Shumway and his team reported survival of up to 3 weeks after the procedure in dogs.⁷ Concurrent with a better understanding of the principles of tissue rejection, critical

immunosuppressive regimens developed. The Stanford group demonstrated long-term allograft survival in dogs when a combination of azathioprine and corticosteroids was administered after transplantation.⁸

In 1964, the first heart to be transplanted into a human recipient was performed by James Hardy⁹ using a chimpanzee donor heart. In 1967, the first human-to-human heart transplant was performed by Christian Barnard in Cape Town, South Africa.¹⁰ The patient, a 57-year-old man with ischemic heart disease, died on postoperative day 18. Soon thereafter, Shumway and the Stanford group performed the first successful cardiac transplant in the United States.¹¹ Additional attempts at cardiac transplantation were made without long-term success, resulting in decreased enthusiasm as the problems of acute rejection and infection became more apparent. Along with Stanford, only a handful of centers worldwide continued performing heart transplants. During this time and over the next decade, the outcomes improved as patient selection criteria were refined and postoperative care advanced. In 1973, Philip Caves and associates¹² introduced percutaneous endomyocardial biopsy, which allowed early diagnosis and treatment of acute rejection. The advancement of immunosuppression, including the use of antithymocyte globulin, offered prophylaxis and treatment for acute rejection.¹³ The introduction of cyclosporine in 1980 was particularly key in the success of cardiac transplantation. Early studies in the United Kingdom by Roy Calne and associates¹⁴ and in the United States by the Stanford group demonstrated its efficacy.¹⁵ Ultimately, combined immunosuppression regimens consisting of cyclosporine or tacrolimus, azathioprine, and prednisone led to long-term patient survival.

The early success of cardiac transplantation played a key role in increasing the number of heart transplant programs worldwide. In turn, the number of transplant procedures performed yearly grew rapidly in the late 1980s and reached its peak by the early 1990s.¹ Ongoing advances in surgical technique, organ preservation, and immunosuppression continue to yield better outcomes in the modern era of heart transplantation.

INDICATIONS AND EVALUATION FOR HEART TRANSPLANTATION

Recipient Selection

Over the years, selection criteria have emerged to identify patients who will benefit most from heart transplantation. The early reports of long-term survival after transplantation validated the effectiveness of transplantation as a treatment for end-stage heart failure such that it is now considered the gold standard for heart failure surgical treatment. The increasing use of ventricular assist devices (VADs) accounts for the decreasing mortality rate of patients on the waiting list, specifically status 1A patients. Because outcomes have improved, recipient selection has become more liberal. The resulting increase in waiting list size has not been matched by an increase in the donor pool. Even with a corresponding liberalization of donor selection criteria, yearly

donor organ allocation numbers 2400 in the United States.² This disparity between the growing demand for organs and a limited donor pool has led to careful reevaluation of recipient selection criteria, as well as exploration of alternative medical and surgical therapies for heart failure. It is clear that organs must be allocated in the most rational and judicious manner possible.

The process of selecting appropriate candidates for cardiac transplantation has become increasingly formalized. Instituting a recipient selection meeting has become standard. Before this meeting occurs, candidates for listing should have their clinical history carefully reviewed and a panel of laboratory and supplementary tests performed (Box 98-1). The process of selecting patients should be as objective as possible. The selection committee should include physicians, nurses, coordinators, dietitians, social workers, and physical therapists.

Common indications include New York Heart Association (NYHA) class III or IV heart failure refractory to maximal medical therapy; debilitating ischemia not amenable to interventional or surgical revascularization; or recurrent, symptomatic ventricular arrhythmias refractory to medical therapy, implantable cardioverter defibrillator (ICD) therapy, and surgical treatment.¹⁶ Asymptomatic patients with severe left ventricular dysfunction alone or patients who are adequately managed with medical therapy should not be considered for transplantation.

For ambulatory patients, important techniques of risk stratification have been developed to identify those at low, moderate, or high risk for mortality while awaiting transplantation. Peak exercise oxygen consumption, or VO_2 , is a measure that correlates well with waiting list mortality.¹⁷ Current International Society for Heart and Lung Transplantation (ISHLT) guidelines suggest that patients who tolerate beta blockade qualify for listing if they have a VO_2 up to 14 mL/kg/min. Those who do not tolerate beta blockade qualify if their VO_2 is up to 12 mL/kg/min.¹⁸ In support of routine repeat cardiopulmonary testing were two previous studies that showed a correlation between increases in peak VO_2 on serial exercise testing and improved survival for listed cardiac transplant patients.^{19,20}

In addition to VO_2 , Aaronson and colleagues²¹ at Columbia University have derived the Heart Failure Survival Score (HFSS) to risk-stratify ambulatory patients awaiting heart transplantation. The HFSS may be particularly useful in patients whose VO_2 is ambiguous.¹⁸ The HFSS has two components. The noninvasive component is composed of seven parameters: diagnosis of ischemic cardiomyopathy, resting heart rate, left ventricular ejection fraction (LVEF), mean blood pressure, peak VO_2 , serum sodium, and presence of intraventricular conduction delay. The invasive component is composed of eight parameters: diagnosis of ischemic cardiomyopathy, resting heart rate, LVEF, mean blood pressure, peak VO_2 , serum sodium, presence of intraventricular conduction delay, and mean pulmonary capillary wedge pressure. Both models can be used to identify a patient's pretransplant mortality risk. Koelling and colleagues²² retrospectively reviewed a database of 524 patients undergoing heart failure evaluation and showed that the HFSS

BOX 98-1 Evaluation of Potential Cardiac Transplant Recipients

PHASE I: ASSESSMENT OF CANDIDACY

General Information

- History and physical examination
- Complete blood cell count with differential and platelet count
- Blood chemistry panel
- Liver function tests
- Renal function panel
- Prothrombin and activated partial thromboplastin time
- Urinalysis
- Chest radiograph
- Pulmonary function test

Assessment of Cardiac Function

- Electrocardiography
- Echocardiography
- Radionuclide ventriculography*
- Right-sided heart catheterization*
- Left-sided heart catheterization*
- Endomyocardial biopsy*
- Peak exercise oxygen consumption (VO₂) testing

Screening Tests

- Stool guaiac (three times)*
- Mammography*
- Prostate specific antigen screening*
- Papanicolaou smear*
- Bone densitometry*
- Carotid duplex*

Infectious Disease Screening

- Hepatitis B surface antigen
- Hepatitis B and hepatitis C virus antibodies
- Human immunodeficiency virus serology
- Human T cell leukemia/lymphoma virus (HTLV-1 and HTLV-2) serology
- Cytomegalovirus IgM and IgG titers
- Toxoplasma serology
- Epstein-Barr virus serology
- Rapid plasma reagin
- Purified protein derivative testing

PHASE 2: PRETRANSPLANT DATA

- Blood type and antibody screening
- HLA-DR typing
- Panel-reactive antibody screening
- 12-hour urine collection for creatinine clearance and total protein

*Performed if indicated by history, age, or physical examination.
HLA, Human leukocyte antigen; Ig, immunoglobulin.

continues to provide important prognostic information in patients with heart failure with or without beta blocker therapy. In addition, the HFSS has been found to be better than VO₂ when applied to all genders and races.²³

Recent advances in medical therapy for patients with heart failure have resulted in improved patient survival rates. In 2001, the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial found that

TABLE 98-1 Underlying Diagnoses of Adult Heart Transplant Recipients 2006–6/2012

Diagnosis	Percentage of Recipients (%)
Cardiomyopathy	54
Coronary artery disease	37
Valvular disease	2.8
Retransplantation	2.5
Congenital heart disease	2.9
Other causes	0.9

From Lund LH, Edwards LB, Kucheryavaya AY, et al: *The Registry of the International Society for Heart and Lung Transplantation: Thirtieth Official Adult Heart Transplant Report—2013; focus theme: age*. *J Heart Lung Transplant* 32(10):951–964, 2013.

treating patients with severe heart failure with carvedilol reduced the 1-year mortality rate to 11% compared with a placebo mortality rate of 19%.²⁴ Although no randomized trials comparing heart transplantation with medical therapy have been performed, it is clear that in some cases, medical therapy yields short-term outcomes as good as or better than cardiac transplantation. However, because the greatest mortality risk associated with transplantation occurs in the first year, long-term follow-up is needed to compare late survival in medically treated cohorts with that in transplanted cohorts. Freudenberger and coworkers²⁵ developed a decision analytic model that simulated a randomized clinical trial comparing optimal medical therapy (OMT) with heart transplantation therapy for each individual NYHA class. The authors showed that OMT was superior to heart transplantation for NYHA classes I, II, and III. They also demonstrated life expectancy gains of 113 months, 38 months, and 6 months, respectively. However, heart transplantation was more beneficial than OMT in NYHA class IV patients, with a gain in life expectancy of 26 months.

The most common diagnoses leading to heart transplantation in adults are idiopathic dilated cardiomyopathy and ischemic cardiomyopathy (Table 98-1). Comparison of the 2013 registry of the ISHLT data with the corresponding 2007 registry data reveals new trends. The percentage of recipients with the diagnosis of cardiomyopathy has increased from 48% to 54%. The percentage with coronary artery disease has decreased from 43% to 37%. The diagnosis of valvular, retransplant, and congenital disease has remained relatively stable at 2.8%, 2.5%, and 2.9% respectively. Importantly, survival after transplantation is related to the underlying diagnosis. Risk factors for 1-year mortality include a history of congenital heart disease, prior heart transplant, dialysis, transfusions, ventilator support, and hospitalization. Female donor to male recipient transplants had a higher risk of mortality as well. Five-year mortality risk factors are similar to that of 1-year mortality, but with the added risk of pregnancy, diabetes, and obesity. Finally, at 15 to 20 years, data regarding risk factors for mortality are limited. What is seen is an increased risk with retransplant; however, congenital recipients have better long-term survival than other diagnoses.²

Other studies have shown controversial results. In the United Kingdom, Aziz and colleagues²⁶ performed a retrospective study of 220 heart transplant recipients and compared long-term survival rates of patients with underlying diagnoses of ischemic heart disease and dilated cardiomyopathy. At 5 years, the survival rates were 96% in the dilated cardiomyopathy cohort and 47% in the ischemic heart disease cohort. At 10 years, the survival rates were 92% in the dilated cardiomyopathy cohort and only 29% in the ischemic heart disease cohort. This provocative study suggests that the benefit of transplantation may be greater in patients with dilated cardiomyopathy. The risk of retransplantation for a recipient is also not clear. In one study, cardiac retransplants performed from January 2003 to December 2006 showed improved survival outcomes compared with those in previous eras, with an 82% 1-year survival rate and 75% 3-year survival rate, both similar to rates seen in primary transplant recipients.²⁷ Atluri and coworkers²⁸ conducted a retrospective review of 709 heart transplant patients at the University of Pennsylvania, 15 of whom received retransplants. The authors demonstrated an 86% 1-year survival rate and a 71% 5-year rate for the retransplant recipients, which were similar to the primary transplant patients' survival rates of 90% and 79%, respectively.¹ Revisiting these outcomes using the ISHLT and United Network for Organ Sharing (UNOS) databases will be necessary on a periodic basis to help guide recipient listing decisions. Absolute and relative contraindications to cardiac transplantation are listed in [Box 98-2](#).

BOX 98-2 Recipient Contraindications to Heart Transplantation

ABSOLUTE CONTRAINDICATIONS

- Pulmonary hypertension (PVR > 6 Wood units despite maximal therapy)
- Significant irreversible renal dysfunction (e.g., creatinine clearance < 50 mg/mL/min)
- Significant irreversible hepatic dysfunction (e.g., bilirubin > 3.0 mg/dL)
- Active malignancy

RELATIVE CONTRAINDICATIONS

- Active infection (except in the setting of severe device complication, which is a status 1A criterion)
- Age older than 65 years
- Peripheral vascular disease not amenable to surgical or percutaneous therapy
- Diabetes mellitus with secondary organ damage
- Severe lung disease
- Uncorrected abdominal aortic aneurysm greater than 4 to 6 cm
- Systemic infection with immune suppression risk (human immunodeficiency virus, hepatitis B virus, cytomegalovirus)
- Obesity
- Osteoporosis
- Active peptic ulcer disease
- Substance abuse
- Psychiatric disorder
- Noncompliance with medical care

PVR, Pulmonary vascular resistance.

Noncardiac organ dysfunction plays a large role in recipient selection. Pulmonary hypertension continues to be an absolute contraindication to adult cardiac transplantation. Currently, a pulmonary vascular resistance (PVR) greater than 6 Woods units despite maximal vasodilator therapy is considered an absolute contraindication.¹⁸ The increased PVR presents a large load for the donor right ventricle, which often has mild dysfunction secondary to ischemic time. Those with elevated PVRs benefit more from a combined heart-lung transplant. Further details on heart-lung transplantation can be found in [Chapter 99](#). Renal insufficiency is associated with early mortality after heart transplant, especially if dialysis is instituted either preoperatively or postoperatively.^{29,30} Analysis of the UNOS database by Schaffer and coworkers clearly shows that patients with severe renal failure benefit from heart-kidney transplantation. This benefit is especially strong for those on dialysis.³¹ Hepatic failure also is associated with poor outcomes. As such, combined heart-liver transplants have been accepted as a treatment modality for these patients. Cardiac indications for heart-liver transplants at the time of transplant included restrictive cardiomyopathy (38%), congenital heart disease (21%), idiopathic dilated cardiomyopathy (17%), ischemic cardiomyopathy (8%), and hypertrophic cardiomyopathy (8%). Hepatic indications included cardiac cirrhosis (43%), amyloidosis (28%), hepatitis-induced cirrhosis (10%), metabolic disease (5%), and hemochromatosis (4%). In their analysis of the UNOS database, Schaffer and coworkers noted that the incidence of waiting list mortality was higher in heart-liver candidates, but survival was not different. Further analysis showed that undergoing a heart-liver transplant was associated with enhanced survival compared with undergoing a heart transplant alone.³²

The consideration of heart transplantation for recipients with human immunodeficiency virus (HIV) has been controversial. However, with the advent of effective antiretroviral therapy, a 10-year survival rate of 90% can be expected.³³ To date, there have been a few case studies, the largest of which reported on seven HIV-positive patients who received a heart. The survival rate at 5 years follow-up for this group of patients was 100%.³⁴ Further review of outcomes for this patient population is necessary to ensure equivalent survival to HIV-negative patients. The allocation of donor hearts to recipients with known malignancy is also controversial. The ISHLT listing guidelines published in 2006 indicated that those patients with skin cancer, cancers in remission for 5 years, and low-grade cancer were acceptable for transplant candidacy.¹⁸ Possible candidates for cardiac transplant should have appropriate screening studies performed, including prostate specific antigen, mammographic screening, colonoscopy, and Papanicolaou smear. For those with a known history of malignancy, close cooperation with oncology is required to ascertain the prognosis of the patient and adjunctive management.

Increasingly liberal acceptance of other comorbidities is expanding recipient lists. Diabetes mellitus is increasing in the general population and now constitutes 10% of patients undergoing transplantation.³³ A review of the UNOS database revealed that survival for patients with

uncomplicated diabetes mellitus was similar to that of heart transplant recipients without diabetes.³⁵ Amyloidosis is another disease that has been a relative contraindication to heart transplantation. Our center, as well as others, has adopted protocols to determine which patients with amyloidosis would be eligible for a heart transplant. General exclusion criteria include involvement of more than two organs, creatinine that is elevated above 2.0 mg/dL, and an alkaline phosphatase level higher than 250 U/liter. Patients with significant autonomic instability also should be excluded. The results for this cohort are promising, but further review of data is needed.³³ The age requirement for transplant has also been changing. In the 2013 ISHLT report, the number of patients in the 60- to 69-year-old range and the 70 years and older range has increased in comparison with the 1996-2005 cohort. Survival with increasing age is similar in the first five years, excluding those in the older than 75 years cohort.² The Scientific Registry of Transplant Recipients (SRTR) database confirms that survival in older cohorts is similar to that of younger recipients.³⁶ Patients older than 65 years also have a decreased risk of rejection, likely because of physiologic aging of the immune system. This is reflected in the increased rate of infections and malignancy in this older group.³³

To increase the availability of heart transplantation as an option for older patients, extended criteria cardiac transplantation (ECCT) was started at several centers, most notably by Hillel Laks and colleagues at the University of California, Los Angeles.³⁷ ECCT patients were offered organs that were not normally used for transplantation. The initial results were promising with similar early survival for non-ECCT recipients, but longer term data were needed.³⁸ Comparison between ECCT patients and destination therapy left ventricular assist device (LVAD) patients at Duke University Medical Center revealed similar 1-year survival. However, at 3 years, overall survival was better for the ECCT group.³⁹ A study looking at ECCT in the UNOS database revealed similar 1-year survival of 89% versus 86% for standard criteria versus ECCT. However, at 3 years, there was a significant decrease in survival (66% vs. 77%) for ECCT patients compared with standard criteria patients.⁴⁰ The data appear to argue for liberalized use of ECCT to increase the availability of heart transplantation. Other relative contraindications to transplantation include obesity (body mass index [BMI] > 32), osteoporosis, substance abuse, clear history of medical noncompliance not related to socioeconomic difficulties, and lack of dedicated social support.^{41,42}

In summary, the decision to list a patient for cardiac transplantation requires examination of multiple medical, psychological, and social factors by the selection committee. Because of the scarcity of donor hearts as well as the need for lifelong medical care, the recipient candidate should be selected for optimal success in the context of increasing indications for cardiac transplantation.

Allosensitization in the Heart Transplant Recipient

ABO blood typing is performed on all candidate recipients. In addition, candidate recipients undergo screening

to establish an anti-human leukocyte antigen (anti-HLA) antibody profile. This is referred to as the panel reactive antibody (PRA) test. The PRA is expressed as a percentage of the population against which the recipient has developed antibodies.⁴³ In some centers, a PRA greater than 10% prompts direct testing of a prospective recipient's serum against a prospective donor's lymphocytes.⁴⁴ This is referred to as a crossmatch. A PRA greater than 10% signifies allosensitization. A PRA of greater than 80% indicates a high likelihood that the recipient will have antibodies to a donor.⁴⁵ PRA should be seen as a screening test and not an actual quantitative measurement. Loh and colleagues followed cardiac transplant recipients with a PRA of greater than 25% and showed decreased survival in these patients versus recipients with a PRA of less than 25%.⁴⁶ A PRA greater than 11% was also shown to be a predictor of earlier and more clinically severe rejection when the UCLA Heart Transplant Group retrospectively reviewed pretransplant PRA screens from 311 patients.⁴⁷ Sensitized recipients have a significantly lower 3-year survival compared with those who are not sensitized. This holds true even if the recipient has a negative donor-specific crossmatch.

Newer methods of determining allosensitization in candidate recipients are coming to the forefront. In particular, calculated PRA (cPRA) has emerged as a possibility for traditional PRA calculation. It is derived from HLA frequencies in the 12,000 kidney donors in the United States. It equals the percentage of possible donors that may have one or more HLA antigens that are not compatible with a given recipient. Because it is derived from known crossmatch incompatibility, it may be more accurate than a traditional PRA screening test. Another method of determining possible allosensitization is the virtual crossmatch (VXM). Essentially, the recipient's complete HLA antibody profile is compared with the possible donor's complete HLA antigen profile to determine a match.⁴⁹ To be able to perform it correctly requires a complete identification of the recipient's antibody profile. Although some false negatives and false positives can occur, the use of a VXM strategy can increase the number of transplants for sensitized patients, especially when donors from outside the immediate region are considered. The VXM has a positive predictive value of 79% and a negative predictive value of 92%.⁵⁰ The risk of antibody-mediated rejection in negative VXM transplants is very low.⁵¹

The frequency of PRA testing varies from center to center. However, certain guidelines can be followed. For patients without detectable antibodies, PRA testing should be done every 6 months.⁵² Patients who have demonstrated detectable antibodies should be tested every 3 months.⁵² For patients who have had an infection or blood transfusion, the antibody levels should be checked within 1 to 2 weeks. Patients who have had a VAD placed should have their PRA levels checked every 1 to 2 months.⁵² Outcomes for heart transplant are better associated with lower PRA levels rather than peak levels.⁴³

Managing allosensitization also varies from center to center. To reduce a potential recipient's antibody load, administration of plasmapheresis, intravenous immunoglobulin (IVIG), and immunosuppressive drugs is

pursued.⁵³⁻⁵⁷ A study performed in 1994 first showed the effectiveness of plasmapheresis, reducing a recipient's PRA from 92% to 10%.⁵⁸ Plasmapheresis was continued for at least 2 weeks after transplantation, and the PRA level remained low. At Columbia University, the superiority of IVIG (one to three monthly courses of 2 g/kg, divided in four daily doses) over plasmapheresis (administered as one to two monthly courses, two to three times per week) was shown in terms of greater reduction in IgG anti-HLA class I.⁵⁹ The study also demonstrated that recipients who received one or two courses of IVIG (2 g/kg) had a mean duration of 3.3 months on the cardiac transplantation waiting list as opposed to 7.1 months for those not receiving IVIG therapy. The Columbia group also suggested that IVIG (2 g/kg) had a better safety profile than plasmapheresis based on the fact that plasmapheresis-treated recipients had more systemic infections and episodes of systemic anaphylaxis (defined by hypotension with pressor support requirement). IVIG has the added benefit of protecting from infection.⁶⁰ Itescu and colleagues supplemented IVIG therapy with intravenous cyclophosphamide pulse therapy before cardiac transplantation and as part of a triple immunosuppressive therapy (cyclosporine-based) regimen and demonstrated that this therapy significantly reduced immunologic markers of alloreactivity, prolonged rejection-free intervals, and decreased overall cumulative frequency of rejection.⁵⁴ The authors also concluded that cyclophosphamide was superior to mycophenolate in reducing rejection in sensitized recipients.

Leech and coworkers established that the combination of plasmapheresis and IVIG therapy in presensitized cardiac recipients reduced T cell and B cell PRA levels as well as crossmatch positivity.⁶¹ They concluded that the combined treatment allows a successful outcome in the sensitized cardiac recipient. However, it was noted that there was an increased risk of rejection. Rituximab is increasingly being used in sensitized cardiac transplantation recipients. A chimeric anti-CD20 monoclonal antibody, rituximab decreases B cells and has no effect on plasma cells and, thus, no immediate effect on circulating antibody levels.⁶² It is often used for recipients refractory to other forms of desensitization.⁶³ Guidelines for identification and pretreatment of sensitized patients awaiting cardiac transplantation, as well as for treatment during and after the surgery, are outlined in [Box 98-3](#).

HLA typing of the prospective recipient may be done before transplantation. However, prospective matching of recipient and donor HLA antigens is not routinely performed because it delays the donor operating room time by 4 to 8 hours.

Recipient Management after Listing

During the time in which the patient is awaiting transplantation, optimal medical management should be continued. The patient should be seen by a cardiologist regularly. During this time, the patient should also be enrolled in cardiac rehabilitation. The better the patient's physical state heading into the transplant is, the less likely complications will occur.

As a patient's heart failure becomes more severe, oral medical therapy becomes inadequate. At this time,

BOX 98-3 Identification and Treatment of Sensitized Patients

IDENTIFICATION

- Detailed medical history, including history of previous transplants, blood transfusions, and pregnancies; human leukocyte antigen (HLA) typing for HLA class I (A, B) and class II (DR, DQ) within 3 months prior to listing
- Autoantibody crossmatch without dithiothreitol (DTT)
- Panel-reactive antibody (PRA) using complement-dependent cytotoxicity and solid phase assays (sensitized when PRA > 10%)
- If positive for antibodies against C, DQA, or DP loci, then also type for HLA-C, -DQA, and -DP
- If initial autoantibody results are positive, crossmatch with DTT to identify antibody isotype

PREOPERATIVE TREATMENT FOR PRA GREATER THAN 50%

- Evaluate response to intravenous immunoglobulin (IVIG) with in vitro IVIG inhibition assay
- If patient is hospitalized, adjunctive plasmapheresis should be considered
- IVIG (1 g/kg, with a maximum of 70 g) twice monthly for up to 6 months
- Rituximab administered via central line or peripheral line—first infusion is at 50 mg/hr increasing until a maximum of 400 mg/hr is reached; subsequent infusions at 100 mg/hr increasing to 400 mg/hr as tolerated
- Success of antibody reduction monitored by HLA laboratory (levels obtained before first dose of IVIG and before and after each subsequent IVIG infusion) every 2 weeks
- Post-IVIG testing includes PRA and specificity with and without DTT on full-screen panel (T and B cells) for classes I and II

PERIOPERATIVE AND POSTOPERATIVE TREATMENT OF SENSITIZED PATIENTS

- On bypass: one-volume plasmapheresis, reconstituting with 5% albumin (50%) and fresh-frozen plasma (50%)
- Rabbit antithymocyte globulin (1.5 mg/kg IV): first dose after hemostasis achieved in operating room (OR); repeat dosing on postoperative days (PODs) 2, 3, 5, and 7
- Methylprednisolone (10 mg/kg IV, maximum 500 mg) after hemostasis achieved in OR and 2.5 mg (maximum, 125 mg) IV every 8 hours, three times
- IVIG 2 g/kg (maximum, 140 g) divided into two doses on consecutive days in intensive care unit
- Rituximab as outlined in preoperative section
- Mycophenolate mofetil (1000 mg PO twice in POD 1)
- Oral prednisone (1 mg/kg divided into two doses, POD 2)
- Tacrolimus (0.5 mg PO twice a day, PODs 1 to 5)
- Plasmapheresis POD 7, and every other day for four treatments thereafter

institution of intravenous therapy is necessary. This includes the use of dopamine, dobutamine, or milrinone. Dopamine, a sympathomimetic catecholamine, has both alpha and beta agonist activity and should be used at dosages of less than 5 µg/kg/min; at higher dosages, its arrhythmogenic and renal vasoconstrictive effects predominate. Dobutamine, a β_1 -adrenergic agonist, is most effective at dosages of less than 10 µg/kg/min. Milrinone, a phosphodiesterase inhibitor with inotropic and vasodilator effects, is effective at dosages of up to 0.5 µg/kg/min. Often, a combination of these medications is used. The use of short-term intravenous dobutamine and milrinone has been found to have an adverse effect on survival in the treatment of acute decompensated heart.⁶⁴ As such, the American College of Cardiology Foundation and American Heart Association discourage their routine use in patients with stage D heart failure and patients without evidence of shock or threatened end-organ perfusion. The institution of chronic intravenous inotropic therapy may be reasonable either for patients with cardiogenic shock awaiting definitive therapy or for patients with stage D heart failure, especially those refractory to guideline-directed medical therapy awaiting mechanical circulatory support (MCS) or heart transplantation.⁶⁵

If patients continue to do poorly despite pharmacologic maneuvers, MCS becomes an important option to bridge to transplantation (BTT). MCS devices may be broadly categorized as either short term or long term. Short-term devices include intra-aortic balloon pump (IABP), percutaneous VAD, paracorporeal VAD, and venoarterial extracorporeal membrane oxygenation (VA-ECMO). IABP counterpulsation reduces afterload and augments diastolic coronary perfusion. For this reason, it is especially useful in patients with ischemic cardiomyopathy. These devices can be left in place only for a short period of time (usually several days) and are not effective if left ventricular ejection is severely compromised. There is a risk for infectious complications associated with IABP use, and the 1-year mortality rate is increased in heart transplant recipients who have previously been supported with an IABP.¹

Percutaneous VADs, such as the Impella⁶⁶ and the Tandem Heart,⁶⁷ have been shown to be effective in treating severe cardiogenic shock. However, no data have shown an increase in survival with these devices as primary therapy. Severe, refractory cardiogenic shock can also be treated with VA-ECMO. By virtue of their temporary nature, all short-term devices should be a bridge to recovery, to decision, to transplantation, or to long-term device implantation. Early in the experience, temporary circulatory support was high risk, with a detrimental effect that continued into the posttransplant period. Taylor and associates reported a 238% increase in risk of mortality at 1 year in the 52 patients who underwent BTT between 2002 and 2005.¹ Even with increasing experience—163 patients between 2006 and 2011—the requirement for temporary circulatory support still imparted a 180% increase in the risk of mortality at 1-year post transplantation.²

With the development of improved mechanical assist devices, long-term MCS has become an invaluable tool in the management of end-stage heart failure. The

results of the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial, which compared 1- and 2-year survival rates of patients with heart failure who were ineligible for transplantation treated with OMT versus LVAD placement, were encouraging.⁶⁸ The investigators found a 25% 1-year survival rate and an 8% 2-year survival rate in the medical therapy group, compared with a 52% 1-year survival rate and a 23% 2-year survival rate in the LVAD group. Based on this study, it was clear that developing a VAD with fewer complications might lead to greater 2-year survival.

In 2007, the Investigation of Nontransplant-Eligible Patients Who Are Inotrope Dependent (INTrEPID) trial, a prospective nonrandomized study, further validated the survival benefit of LVAD placement versus OMT with survival rates of 46% versus 22% at 6 months and 27% versus 11% at 1 year, respectively.⁶⁹ Patients in the OMT group did not experience any improvement in NYHA functional class, whereas 85% of LVAD patients experienced either minimal or no symptoms. The authors concluded that no further randomized trials should be conducted comparing these two groups because of the overwhelming survival advantage of LVAD versus OMT seen in both REMATCH and INTrEPID trials.

As a follow-up to the REMATCH trial, Slaughter and colleagues evaluated the efficacy of the Heartmate II (Thoratec, Pleasanton, CA) and demonstrated superiority of the continuous flow LVAD as compared with the pulsatile Heartmate XVE. Survival at 2 years in the continuous flow group was 67% compared with 59% in the pulsatile group. Additionally, reoperation because of pump-related complication (device repair, replacement, or explantation including for transplantation) occurred in 24 of 66 patients (36%) receiving a pulsatile device but in only 13 of 134 (10%) of continuous flow LVAD recipients.⁷⁰

Predictably, the effect of LVAD on waiting list survival has been profound. A preliminary study published in 2002 by Aaronson and colleagues⁷¹ retrospectively compared the use of LVADs and high-dose inotropes as BTT in 104 patients at Columbia-Presbyterian Medical Center. Survival to transplantation was 81% in the LVAD group, compared with 64% in the inotrope group. Dardas and coworkers confirmed the benefit of LVAD implantation in an analysis of the Scientific Registry of Transplant Recipients (SRTR) between 2005 and 2010.⁷² Patients who received an LVAD with elective status 1A had a significantly lower cumulative hazard of adverse events (death or delisting because of illness), at 1% within 30 days, compared with medically treated status 1A patients with or without IABP, at 6% within 30 days. Patients with an implanted LVAD who were status 1B also had reduced hazard of adverse events compared with status 1B medically treated patients. On the basis of the low risk of death or illness resulting in delisting among patients with an implantable LVAD, the authors suggested downgrading these patients to a status between 1B and 2. On the other hand, paracorporeal VADs were found to have sustained risk justifying status 1A listing indefinitely.

Wozniak and colleagues reviewed the UNOS database for patients receiving VAD BTT between 1998 and

2012.⁷³ Patients who received any form of ventricular support (either isolated LVAD or biventricular assist device [BiVAD] support) had similar waiting list survival compared with those requiring only inotropic support. However, in patients who received an isolated LVAD, waiting list survival was significantly improved compared with the cohort of medically treated patients including those requiring IABP placement.

Whereas the waiting list outcomes are clear, the effect of LVAD implantation on posttransplantation survival has been controversial. Between 2002 and 2005, pulsatile VAD implantation was associated with a 27% increased relative risk of mortality 1 year post transplantation.¹ This difference in mortality may be attributable to differences among devices, as Russo and colleagues determined in a multivariate analysis of the UNOS database between 2001 and 2006. Patients with extracorporeal VADs had significantly reduced risk-adjusted 90-day graft survival compared with intracorporeal and paracorporeal devices. Posttransplantation survival was similar among patients who were not bridged with a VAD and those receiving either an intracorporeal or a paracorporeal device.⁷⁴

Posttransplant mortality at 4 years among patients bridged to transplantation with a pulsatile LVAD fell significantly as experience developed not only with the operation itself but also with the management of these patients. Those who were bridged to transplantation between 2000 and 2004 were at 30% greater risk of mortality than those who received pulsatile devices between 2004 and 2008. In the latter period, Nativi and associates reported similar outcomes between patients who underwent BTT with pulsatile and continuous-flow devices, and these were not significantly different from patients who did not receive an LVAD.⁷⁵ Contemporary registry data have confirmed this finding with no significant difference in intermediate survival up to 6 years post transplantation among patients who preoperatively had an LVAD, patients who required inotropic support, and patients requiring neither.²

In spite of the benefits of pretransplant implantation on waiting list outcomes and the growing evidence that modern LVADs do not necessarily affect posttransplantation outcomes, the use of LVADs is not without risk. First, patients are exposed to the potential morbidity of device complication; however, this may be acceptable given the improved survival on the waiting list. Of the potential complications that may prompt status 1A listing for heart transplantation (i.e., thromboembolism, device infection, and life-threatening arrhythmia), only infection was associated with worse survival at both 1 year and 10 years post transplantation.⁷⁶

Another potential difficulty with LVAD implantation is the associated increase in PRA.⁷⁷ Although this increase in PRA could be attributable to transfusion of cellular blood products,⁷⁸ the avoidance of leukofiltered cellular blood products has not been shown to be of benefit.^{48,79} LVAD type appears to have an impact on the development of allosensitization related to the interaction between the patient and the device as has been shown in single-institution retrospective studies.^{80,81} The impact of PRA on the subsequent management of patients, includ-

ing the need to reduce HLA antibodies, has been discussed previously.

BiVAD implantation is associated with significantly worse outcomes than LVAD implantation alone.^{82,83} Additionally, there are patients for whom LVAD may be contraindicated (e.g., those with aortic insufficiency, acquired VSD, or right ventricular failure). The total artificial heart was thus conceived as a means to provide biventricular support. In 2004, Copeland and colleagues reported a 79% success rate in BTT, which was superior to historically matched controls.⁸⁴ However, the overall experience with the total artificial heart remains limited, and this remains an area of active investigation.

ORGAN PROCUREMENT AND PRESERVATION

Donor Selection

The selection of donors for cardiac transplantation follows the guidelines outlined in [Box 98-4](#). The regional organ procurement organization is the first group to begin the selection process, at which time information is collected regarding cause of death, body size, ABO blood type, serologies (including human immunodeficiency virus, hepatitis B virus, and hepatitis C virus), and clinical course. A transplant physician then performs a secondary screen. This includes a review of relevant history, baseline electrocardiogram, chest radiograph, laboratory data, echocardiogram, and in some cases cardiac catheterization. The final screen is performed by the procuring surgeon at the donor hospital site.

Potential donors must meet standard requirements for brain death. Donors who died from cardiac causes, have had an acute coronary event, have intractable arrhythmias, or have deleterious structural abnormalities should be excluded.⁸⁵ In addition, donors with a history of severe chest trauma causing severe cardiac contusion with resulting cardiac depression should be excluded. The importance of left ventricular hypertrophy is being reevaluated in light of the shortage of donor organs. Previously, posterior wall (PW) and interventricular

BOX 98-4 Cardiac Donor Selection Criteria

- Age younger than 55 years
- No history of chest trauma or cardiac disease
- No prolonged hypotension or hypoxemia
- Meets hemodynamic criteria:
 - Mean arterial pressure greater than 60 mm Hg
 - Central venous pressure 6 to 10 mm Hg
- Inotropic support less than 10 mg/kg/min (dopamine or dobutamine)
- Normal electrocardiogram
- Normal echocardiogram
- Normal cardiac angiography*
- Negative hepatitis B surface antigen, hepatitis C virus, and HIV serologies

*Performed as indicated by donor age and history.

septal (IVS) thickness was expected to be less than 1.2 cm. In a study by Goland and associates, donors with a thickness of up to 1.7 cm showed no decrease in survival, arguing for more liberal use of hearts with left ventricular hypertrophy.⁸⁶ Donor age younger than 55 years is preferable, although on occasion older donors are considered. Many transplant centers, including Stanford University, have become more flexible regarding the donor age criterion. For all male donors older than 45 years and female donors older than 50 years, cardiac catheterization with coronary angiography should be performed to rule out significant coronary artery disease.⁸⁷ Relative contraindications include positive hepatitis B or C serology, sepsis, history of cancer, or prolonged hypotension or hypoxemia.

Reviewing the 2013 data from the ISHLT registry reveals important trends. The use of donors with diabetes mellitus (3.0%) and hypertension (14%) is increasing. Expansion of the donor pool has been achieved by liberalization of other criteria as well, including increasing ischemic time, mild valvular abnormality, and mild coronary disease.⁸⁸ The use of hearts that have undergone longer arrest and resuscitation has also been noted.⁸⁹ Given this recent liberalization, long-term outcomes with these organs for non-ECCT recipients have not yet been determined. In addition, some data indicate that donor characteristics, such as older age and prolonged ischemic time, may interact synergistically to increase recipient mortality risk.⁹⁰

Donor Management

Meticulous and aggressive hemodynamic management of donors can increase the cardiac donor pool.^{91,92} Because all patients have brain death, they are often hemodynamically unstable as a result of neurogenic shock, excessive fluid losses, and bradycardia.^{93,94} Detailed fluid management is required, with intravascular volume replacement given to maintain a central venous pressure (CVP) between 6 and 10 mm Hg. Whereas excessive use of inotropes or vasoconstrictors is frowned on, the use of low-dose dopamine is associated with improved outcomes after heart transplant.⁹⁵ Intravenous vasopressin can be used to help control diabetes insipidus, which is common in patients with brain death. Ventilator settings should be set with the plan to offer the donor lungs for transplant. The settings should be adjusted to, at most, a fractional inspired oxygen of 40% and a positive end-expiratory pressure of 5 cm H₂O to prevent atelectasis. Although some donor organizations have begun to liberalize transfusion triggers, the outcomes are unclear. As such, a minimal hematocrit of 30% should be maintained. The blood should be cytomegalovirus-negative and leukocyte-filtered blood if possible.⁹⁶

Serial echocardiograms should be pursued in the setting of brain injury. A single echocardiogram may provide initial information but likely is not representative of the true function of the heart. Cardiac dysfunction, as confirmed by echocardiogram, occurs in up to 42% of brain-dead patients, and the correlation between these abnormalities and actual pathologic findings is often poor.^{97,98} Placement of a pulmonary artery catheter is

useful in assessing initial cardiac function and the response to therapy. Typical hemodynamic goals include a mean arterial pressure of greater than 60 mm Hg, a CVP of 6 to 10 mm Hg, and a pulmonary capillary wedge pressure of less than 12 mm Hg.

The Papworth group has reported an increase in organ retrieval of 30% by using an aggressive protocol for donor management.^{99,100} This included placement of a pulmonary artery catheter to guide the process of resuscitating the patient and provision of hormonal therapy, including thyroxine,¹⁰¹ cortisol, antidiuretic hormone, and insulin. Using this protocol, most donors originally deemed unacceptable by strict hemodynamic criteria were converted into acceptable donors. The Crystal City Guidelines outline another management strategy for potential organ donors. The algorithm begins with conventional management; correction of acidosis, hypoxemia, and anemia; and appropriate titration of inotropes to maintain adequate organ perfusion. This is then followed by an initial echocardiogram. If the LVEF is greater than 45%, the heart is suitable for recovery. If the LVEF is less than 45%, hormonal resuscitation and hemodynamic management with a pulmonary artery catheter should be undertaken. The heart will be recovered only if appropriate hemodynamic parameters can be reached.⁸⁷

Organ Allocation

Allocation algorithms have been developed to facilitate organ distribution. In the United States, organ allocation is governed by UNOS. The current heart algorithm takes into account medical urgency, time on the waiting list, and blood type.¹⁰² The waiting list status categories (1A, 1B, 2, and inactive) are defined in Table 98-2. Listing can also be modified by age; for example, adolescent donor hearts are preferably allocated to pediatric recipients. Geographic location also plays an important role in the allocation. Prior to 2006, local thoracic organ allocation was performed before regional allocation. After 2006, thoracic organ allocation by UNOS changed such that regional allocation played a larger role. The policy change allowed for greater regional sharing of organs with a goal of increased allocation to status 1A patients and reduced waiting list mortality. As a result of the change in policy, Schulze and coworkers found an overall increase in waiting list time for status 1A and 1B patients of 17.8 days. However, there was a decrease in waiting list mortality after the change (13.3 vs. 7.9%; $P < 0.001$). At the same time, 2-year posttransplantation survival improved (82.7% vs. 85.4%; $P < 0.001$).¹⁰³

Donor and Recipient Matching

Prospective recipients and donors must be ABO blood type compatible, although not necessarily ABO identical.¹⁰⁴ In the past, differences up to and greater than 20% could be tolerated. For recipients whose PVR remains at the upper limit of acceptable, a donor whose body size is at least equal to that of the recipient should be chosen to decrease the likelihood of acute right-sided heart failure.¹⁰⁵ In the case of patients with normal PVR, the lower limit of an acceptable size match is an area of active

TABLE 98-2 UNOS Medical Urgency Status Categories

Status Level	Category
Status 1A	The candidate is admitted to the transplant hospital that registered the candidate on the waiting list, or an affiliated Veterans Administration (VA) hospital, and the candidate also meets at least one of the requirements: 1. Has one of the following MCS devices in place: TAH, IABP, ECMO. 2. Requires continuous mechanical ventilation. 3. Requires continuous infusion of a single high-dose intravenous inotrope or multiple intravenous inotropes, and requires continuous hemodynamic monitoring of left ventricular filling pressures. 4. A candidate who is at least 18 years old at the time of registration, and may or may not be currently admitted to the transplant hospital, may be assigned adult status 1A if the candidate meets at least one of the following requirements: a. Has one of the following MCS devices in place: LVAD, RVAD, BiVAD.* b. Candidate has MCS and there is medical evidence of significant device-related complications.[†]
Status 1B	At least one of the following devices or therapies in place: 1. LVAD, RVAD, or BiVAD. 2. Continuous infusion of intravenous inotropes.
Status 2	All other actively listed patients.
Inactive	Temporarily unsuitable for transplant. The patient will not receive any heart offers.

*The candidate may be registered as adult status 1A for 30 days at any point after being implanted once an attending physician determines the candidate is medically stable. The 30 days do not have to be consecutive. However, if the candidate undergoes a procedure to receive another device, then the candidate qualifies for a new term of 30 days. Any 30 days granted by the new device would substitute and not supplement any time remaining from the previous adult status 1A classification.

[†]Thromboembolism, device infection, mechanical failure, or life-threatening ventricular arrhythmias. A candidate's sensitization is not an acceptable device-related complication to qualify as adult status 1A.

BiVAD, Biventricular assist device; ECMO, extracorporeal membrane oxygenation; IABP, intraaortic balloon pump; LVAD, left ventricular assist device; MCS, mechanical circulatory support; RVAD, right ventricular assist device; TAH, total artificial heart; UNOS, United Network for Organ Sharing.

debate. Jayarajan and associates demonstrated that a donor-to-recipient weight ratio as low as 0.6 may be tolerated in gender-matched patients and in male-to-female heart transplants. However, female-to-male heart transplants were found to have increased hazard of mortality and reduced median survival compared with gender-discordant size-matched individuals.¹⁰⁶ In rare situations, small hearts may be heterotopically transplanted into larger recipients, but the outcomes in these cases are significantly worse than size-matched OHT.¹⁰⁷ In patients with an elevated PRA, either a prospective or a virtual crossmatch may be performed with the potential donor.¹⁰⁸ A positive crossmatch portends a high likelihood of hyperacute rejection, and in such cases the donor organ cannot be accepted for that recipient.

Donor Operative Technique

Retrieval of the donor heart typically occurs as part of a multiorgan procurement. In most cases, the cardiothoracic team must work in conjunction with an abdominal team that is procuring the liver and/or kidneys. Communication between the two teams is essential to prevent unnecessary prolongation of ischemic time. This includes agreeing on a start-time for the procuring teams based on the status of the recipient teams. Delays to donor crossclamp may occur if the heart recipient requires a redo sternotomy, especially in the case of a previous LVAD patient who requires explantation. There are minor modifications to the heart procurement technique when either one lung or both lungs are being procured.

A median sternotomy is performed, and the pericardium is opened longitudinally. The heart is carefully inspected for external signs of trauma, infarction, congenital anomalies, and overall right and left ventricular function. The coronary arteries are palpated to evaluate for coronary artery disease. Significant abnormalities preclude use of the donor heart in transplantation. The ascending aorta is dissected from the pulmonary artery and encircled with an umbilical tape. The superior vena cava (SVC) is mobilized to the level of the azygos vein and is then encircled with a single heavy silk tie and snared loosely. The azygos vein is then doubly ligated, but it is not divided.

When the abdominal procurement team has completed their dissection, 30,000 units of intravenous heparin is administered to the donor. A cannula for infusion of cold cardioplegia is inserted into the ascending aorta and secured. If the lungs are being procured, a pulmonoplegia line is inserted through a purse-string stitch and into the main pulmonary artery. Any central venous lines are withdrawn high into the SVC. The SVC is then snared tightly to limit venous return to the heart. The right heart is decompressed, and the donor is exsanguinated by incising the inferior vena cava (IVC) at the diaphragm ensuring enough of a cuff for implantation of both the heart and the liver. Sufficient length on the SVC and IVC will be needed for later bicaval anastomoses. Blood and perfusate from the liver will drain into the right pleural cavity, and suction should be available to keep the field clear. The left side of the heart is decompressed by incising the left inferior pulmonary vein.

Alternatively, if the lungs are also being procured, the left side of the heart is decompressed by amputating the left atrial appendage. As the heart empties, the aortic cross-clamp is placed and cold crystalloid cardioplegia (10 mL/kg) solution is rapidly infused into the aorta ensuring diastolic arrest. It is important to continually observe the left ventricle for distention. Pulmonoplegia solution is also rapidly infused into the pulmonary artery if the lungs are being procured. While the plegia solutions are being delivered, the thoracic organs are topically cooled with several liters of ice-cold slush.

When the infusions are completed and the heart has been appropriately cooled and arrested, the chest is emptied of the cold slush. The heart is rapidly excised by dividing the four pulmonary veins, the IVC, the SVC, the aorta (as high as possible), and the pulmonary arteries. If the lungs are being procured, a short cuff of left atrial tissue may be retained with the pulmonary veins, and the pulmonary artery is divided at the bifurcation of the left and right pulmonary arteries. Once removed from the donor, the heart is examined for debris, including the possibility of an amputated central venous catheter. It is then rinsed in cold saline and sterilely bagged first in cold preservation solution and then in slush. The heart is then placed in a container filled with cold slush and transported in a cooler designated specifically for this purpose. A section of donor pericardium is additionally harvested in the event that it is needed for reconstruction.

Organ Preservation

Several strategies are used for cardiac preservation during organ retrieval and ischemic storage, including the use of hypothermia, cardioplegia, and preservation solutions.¹⁰⁹ Hypothermia at 4° C to 8° C markedly decelerates metabolism and is used during organ retrieval, storage, and transport.¹¹⁰ Cardioplegia is used to arrest electrical activity of the heart.¹¹¹ Adequate decompression of the ventricles during organ retrieval limits injury to the heart during procurement. The heart may be stored in any of a variety of preservation solutions, which can be broadly categorized as intracellular and extracellular types, based on their ionic composition. Intracellular solutions have a moderate to high potassium concentration and little calcium or sodium, whereas extracellular solutions have a high sodium concentration and a low to moderate concentration of potassium.¹¹² In addition to electrolyte constituents, these solutions often contain impermeants and colloids to prevent the development of intracellular edema. Most contain glucose to prevent intracellular acidosis secondary to anaerobic metabolism. Many contain antioxidant additives to protect against reperfusion injury. The possibility of improving donor heart preservation with additives to the preservation solution is being studied, and rho-kinase inhibitor¹¹³ and small interfering RNA¹¹⁴ have been proposed. In rare cases, preservation solutions are used as alternatives to standard cardioplegia during organ procurement.

Cardiac preservation currently is limited to 4 to 6 hours of cold ischemic storage. Longer ischemic periods adversely affect recipient survival.⁵¹ Most notably, in

February 2007, the U.S. Food and Drug Administration (FDA) approved the clinical use of a system developed by TransMedics, Inc., called the Organ Care System (OCS). OCS involves perfusing donor hearts with warm, oxygenated, nutrient-rich blood while maintaining the organ in a beating, functioning state in transit, with the hope that the heart arrives in a healthier and more dynamic state. The recently completed global clinical trial PROCEED II evaluated the safety and performance of the OCS for the preservation of donor hearts during transplantation, but results have not yet been published.¹¹⁵ Several cardiac transplant recipients have received donor hearts that have undergone OCS and have recovered successfully. Long-term results and the comparison between OCS and standard organ preservation methods have yet to be elucidated.

RECIPIENT OPERATIVE TECHNIQUE

Both orthotopic and heterotopic techniques for clinical heart transplantation are performed. Orthotopic transplantation is performed in most cases, whereas heterotopic transplantation is reserved for cases in which the recipient has significant pulmonary hypertension or the donor is notably smaller than the recipient.

For many years, the technique of Lower, Stofer, and Shumway, described in 1961, was the standard.⁶ This technique, often referred to as the biatrial or standard technique, involves excision of the recipient heart at the mid-atrial level and sewing corresponding anastomoses between the donor and recipient left atrium, right atrium, aorta, and pulmonary artery. This technique permits short operative times and avoids potential complications that result from individual caval and pulmonary venous anastomoses, including but not limited to stenosis and thrombosis. Disadvantages of the method include distortion of atrioventricular geometry, which can result in atrial enlargement, atrioventricular valve insufficiency, impaired atrial function, atrial thrombosis, and sinoatrial node dysfunction.^{116,117} Barnard¹¹⁸ introduced an important modification of the technique in 1968: the incision in the donor heart's right atrium was extended from the opening of the IVC into the base of the right atrial appendage, rather than into the SVC, avoiding the region of the sinoatrial node, which may be injured because of its proximity to the right atrial suture line in the classic orthotopic standard technique.

The standard technique is declining in popularity. Newer techniques, including the "bicaval" and "total" techniques, offer the advantage of better preservation of atrial geometry.¹¹⁹⁻¹²¹ In the bicaval technique, the native recipient's right atrium is excised, and separate SVC and IVC anastomoses are made in addition to the left atrial, aortic, and pulmonary artery anastomoses. The total technique uses separate SVC, IVC, aortic, and pulmonary artery anastomoses as with the bicaval technique. However, rather than use a single left atrial anastomosis, the total technique uses separate right and left pulmonary vein anastomoses. The left atrial remnant is divided longitudinally leaving left and right pulmonary vein cuffs, which are then anastomosed to the left and right

pulmonary vein orifices in the donor heart's left atrium. Technical considerations include shortening of the IVC, kinking of the pulmonary artery, and SVC stenosis; an early series from Stanford University reported a 2.4% incidence of SVC stenosis.¹²² The total technique may be associated with additional complications, including bleeding from inaccessible pulmonary vein suture lines and pulmonary vein stenosis.

The bicaval technique is now the most commonly used anastomotic method with 62.0% of recipients undergoing this operation and 34.7% undergoing biatrial anastomosis in 2007 as compared with 2.3% and 97.6% in 1997.^{123,124} The bicaval technique has been increasing in popularity because of the lower incidence of permanent pacemaker implantation, improved tricuspid valve function, and improved right atrial hemodynamics. With respect to mortality benefit, Weiss and coworkers demonstrated using the UNOS database that although gross mortality was higher in patients undergoing biatrial anastomosis at 24% compared with bicaval anastomosis at 18%, this difference was eliminated after controlling for confounders. However, Davies and colleagues were able to show, in a larger cohort, favorable survival for the bicaval technique compared with both biatrial and total orthotopic techniques.¹²⁴⁻¹²⁷

Orthotopic Standard Technique

In the orthotopic standard technique, the recipient is positioned supine on the operating room table. The chest is entered through a median sternotomy, and the pericardium is opened longitudinally. After heparinization, cardiopulmonary bypass (CPB) is initiated via cannulas in the ascending aorta, SVC, and IVC. Snares are placed around the SVC and IVC for total CPB, and the patient is cooled to 28°C.

Once the donor heart has been brought to the operating room, the recipient heart is excised. The aorta is cross-clamped proximal to the aortic cannulation site. The right and left atrial walls, atrial septum, pulmonary artery, and aorta are divided. The pulmonary artery and aorta should be divided just above the semilunar valves (Fig. 98-1A).

The donor heart is prepared for implantation by excising the tissue between the orifices of the four pulmonary veins leaving a single large opening. The right atrium is then opened, beginning from the lateral aspect of the IVC and extending into the base of the right atrial appendage. The heart is carefully examined for any valvular or congenital anomalies.

In the original description of the standard technique, anastomoses were performed in the following order: left atrium, right atrium, pulmonary artery, and aorta. In an attempt to achieve earlier reperfusion, the sequence of anastomoses may be altered. For example, in the case of prolonged ischemic time, the aortic anastomosis can be performed immediately after the left atrial anastomosis allowing the aortic crossclamp to be removed. The original sequence of anastomoses is described as follows.

The anastomosis of the donor and recipient left atria is performed with a double-armed running 3-0 or 4-0 polypropylene suture. The first stitch is placed in the

recipient left atrium at the level of the left superior pulmonary vein and at the base of the donor left atrial appendage. The suture line is continued around the superior and inferior borders of the left atrium and then tied along the interatrial septum. Once this suture line is complete, the left atrial appendage is cannulated with a line of cold saline to facilitate endocardial cooling. In addition, cold saline is continuously infused into the pericardial well to achieve topical cooling.

The two right atria are anastomosed with a double-armed running 4-0 or 5-0 polypropylene suture (see Fig. 98-1B). The first stitch is placed through the midpoint of the donor septum and through the midpoint of the suture line along the atrial septum. The suture line is continued inferiorly first, and then the superior suture line is completed. The two ends of the suture are tied along the right atrial free wall. Once the right atrial anastomosis is completed, systemic rewarming is initiated.

The donor and recipient pulmonary arteries are trimmed to an appropriate length and anastomosed with a running 4-0 polypropylene suture. The donor and recipient aortas are also trimmed and anastomosed with a running 4-0 polypropylene suture (see Fig. 98-1D).

The ascending aorta and pulmonary artery are cleared of air. The SVC and IVC snares are then released, followed by the aortic crossclamp. De-airing is continued as needed. Transesophageal echocardiography aids in de-airing the heart and assessing cardiac function. The line in the left atrial appendage is removed, and the hole is oversewn. Temporary atrial and ventricular wires are placed in the transplanted heart. The heart is then allowed to recover fully. Defibrillation may be necessary. After at least 30 minutes of reperfusion, the patient is gradually weaned from CPB and the cannulas are removed. Intravenous methylprednisolone (500 mg) is administered. Mediastinal drains are placed, as well as pleural chest tubes if the pleura were opened. The chest is then closed in the standard fashion.

Orthotopic Bicaval Technique

In recent years, the bicaval technique for OHT has become the preferred approach at most transplant centers. The bicaval anastomosis was reported in 1991 by Dreyfus and colleagues.¹¹⁹ Several modifications distinguish it from the standard approach. First, the recipient SVC is cannulated just below the innominate vein junction, and the IVC is cannulated at the diaphragm. Recipient cardiectomy is performed as a two-step procedure. In the first step, the heart is transected at the mid-atrial level, the aorta and pulmonary artery are divided, and the heart is removed. In the second step, the posterior walls of both atria are removed; on the right side, the SVC and IVC are transected at their junction with the right atrium, and on the left side, the left atrium is trimmed, leaving a cuff of tissue around the pulmonary vein orifices (Fig. 98-2A). The donor heart's left atrium is trimmed, leaving a single orifice where the pulmonary vein entry sites had been, and the right atrium remains intact (see Fig. 98-2B). In the bicaval approach, the typical sequence of anastomoses is left atria, venae cavae, pulmonary arteries, and aortas. The left atrial, pulmonary artery, and aortic anastomoses

FIGURE 98-1 ■ Biatrial or “standard” technique for orthotopic heart transplantation. **A**, Cannulation technique is similar to that performed in routine cardiac procedures with central cannulation. Tapes have been placed around the superior and inferior venae cavae, and the aorta has been cross-clamped to exclude the heart from the circulation. The recipient’s heart has been excised at the atrioventricular groove. The superior vena cava (SVC) of the donor’s heart has been ligated, and the left atrial anastomosis has been started. **B**, The left atrial anastomosis has been completed. The incision in the right atrium of the donor heart is curved away from the SVC and the adjacent sinoatrial node. The right atrial anastomosis is begun. **C**, The right atrial, pulmonary artery, and aortic anastomoses are completed. The aortic crossclamp is removed, and the patient is weaned from cardiopulmonary bypass. **D** and **E**, When the heart is fully recovered, the bypass cannulas are removed. (From Baumgartner WA, Reitz BA, Oyer PE, et al: Cardiac homotransplantations. *Curr Probl Surg* 16:1–61, 1979.)

FIGURE 98-2 ■ Bicaaval technique for orthotopic heart transplantation. **A**, Cardiopulmonary bypass is initiated after cannulation of the superior vena cava (SVC), inferior vena cava (IVC), and aorta. The aorta is cross-clamped, and native recipient cardiectomy is performed. A cuff of left atrial tissue is preserved around the four pulmonary vein orifices. **B**, The donor heart is prepared for transplantation. The left atrial tissue surrounding the four pulmonary vein orifices has been excised, leaving a single large orifice. **C**, The left atrial anastomosis is performed. **D**, The IVC anastomosis is completed, and the SVC anastomosis is performed. Once this is completed, the pulmonary artery and aortic anastomoses will be performed.

are performed as described earlier in the standard technique (see Fig. 98-2C). The SVC anastomosis is performed with a running 5-0 polypropylene suture and the IVC anastomosis with running 4-0 polypropylene suture (see Fig. 98-2D).

A further modification to this technique has been practiced at Stanford University by Oyer and associates since 1992, although it was first published in 2001 by Kitamura and colleagues.¹²⁸ The modified bicaaval anastomosis technique for OHT leaves the posterior

portion of the right atrial wall connecting both the SVC and the IVC intact. This modification makes the anastomosis technically easier with respect to proper orientation and eliminates the retraction, tension, or kinking of the venae cavae.

Orthotopic Total Technique

The orthotopic total technique is used at a small number of centers. It is similar to the bicaaval approach except that

during recipient cardiectomy, the left atrial cuff surrounding the pulmonary vein orifices is divided longitudinally into separate right and left pulmonary vein cuffs. Preparation of the donor heart requires separate preparation of the right and left pulmonary veins leaving two orifices on the donor heart's left atrium. Two left atrial anastomoses are fashioned, followed by the bicaval, pulmonary artery, and aortic anastomoses.

Heterotopic Technique

In the heterotopic approach, the donor IVC and right pulmonary veins are ligated, followed by anastomosis of the donor and recipient left atria, SVC, aortas, and pulmonary arteries. SVC and aortic anastomoses are performed in an end-to-side manner, and a short length of graft is used to connect the pulmonary arteries (Fig. 98-3). The heterotopic approach can be used when recipient PVR is markedly elevated given the possibility of acute right-sided heart failure in a donor right ventricle unaccustomed to the pulmonary resistance. In addition, it has been used in cases of donor and recipient size mismatch when medical urgency for transplantation is high.¹⁰⁷ Improvements in mechanical assist devices and a growing experience in their use as BTTs have made the indications for heterotopic heart transplantation almost obsolete.

RECIPIENT POSTOPERATIVE MANAGEMENT

Clinical Management in the Early Postoperative Period

On completion of the transplant, the patient is transported to the intensive care unit. The patient remains mechanically ventilated with continuous monitoring of electrocardiogram, arterial blood pressure, CVP, and pulse oximetry. In most cases, a pulmonary artery catheter is used to further monitor hemodynamics. Temperature, urine output, and mediastinal drain output are monitored as well.

As with other patients undergoing cardiac surgery, dysrhythmias are frequent in the early postoperative period. Junctional rhythms are particularly common after OHT. Because cardiac output of the denervated transplanted heart is primarily rate dependent, the heart rate should be maintained between 90 and 110 beats per minute during the first few postoperative days.¹²⁹ Isoproterenol infusion, theophylline, oral albuterol, and temporary pacing may be used to augment the heart rate. Another option is to place temporary atrial and ventricular pacing leads in the operating suite, allowing for postoperative heart rate adjustment. Less than 5% of patients

have permanent sinus node dysfunction and require placement of a permanent transvenous pacemaker. The rate of sinus node dysfunction may be reduced when the bicaval technique is used.¹²⁹

In most cases, the postoperative course after transplantation is uncomplicated. The patient is extubated when alert and hemodynamically stable, typically within 6 hours of surgery. The patient is gradually weaned from inotropic support over the first few postoperative days. Invasive catheters are removed as soon as possible to reduce the risk for sepsis, and mediastinal drains are removed when drainage has fallen to less than 200 mL/day. Temporary pacing wires are removed approximately 1 week after transplantation, provided that pacing is not required.

Early complications after transplantation include bleeding, depressed global myocardial performance, and right-sided heart failure. Significant hemorrhage may require surgical reexploration. Depressed global myocardial performance is uncommon but may occur in the setting of prolonged organ ischemia or inadequate preservation.¹³⁰ In such cases, aggressive hemodynamic and ventilatory management is necessary, and support from inotropic agents and vasopressors is needed. Hypovolemia, cardiac tamponade, sepsis, and bradycardia can result in depressed myocardial performance and should be treated expeditiously if they are present.

Right-sided heart failure can occur after transplantation, particularly in recipients who have elevated preoperative PVR.¹³¹ In such cases, the donor right ventricle is unable to work against the elevated PVR and begins to fail within hours after transplantation. Aggressive early management may mitigate the consequences of this complication. Intraoperative transesophageal echocardiography should be performed routinely to assess right ventricular function and evaluate for technical failure such as kinking of the pulmonary artery or anastomotic stenosis. Treatment of right-sided heart failure includes correction of any technical problems, optimization of volume status, medical treatment with inotropes, implementation of pulmonary vasodilators (nitroprusside, inhaled epoprostenol, and inhaled nitric oxide), and avoidance of hypercarbia (goal CO₂, <40 mm Hg). Refractory right-sided heart failure may necessitate placement of a right ventricular assist device.

Maintenance Immunosuppression

In addition to careful monitoring of cardiac function during the immediate postoperative period, much focus is placed on institution of immunosuppression. In most cases, immunosuppression is initiated intraoperatively with intravenous methylprednisolone and continued postoperatively with a combination of intravenous and oral medications. Most centers have adopted triple drug combinations of a calcineurin inhibitor (cyclosporine or tacrolimus), an antiproliferative agent (azathioprine or mycophenolate mofetil [MMF]), and a corticosteroid. Immediately after transplantation, many of these medications are administered intravenously, although some must be delivered via nasogastric tube. Once patients are tolerating oral intake, they can be converted to a completely

oral immunosuppressive regimen. Because the risk for allograft rejection is highest in the first several months after transplantation, immunosuppression is most aggressive during this period. If patients remain free of rejection, immunosuppression is gradually decreased over time. Typical immunosuppressive dosing regimens (early and late) are demonstrated in Box 98-5.

Multidrug immunosuppression targets multiple sites in the immune cascade that lead to allograft rejection.¹³² Calcineurin inhibitors block the activity of calcineurin, a calcium- and calmodulin-dependent phosphatase that is required for early T cell activation and interleukin-2 (IL-2) formation. Antiproliferative agents inhibit lymphocyte replication through a variety of mechanisms. Azathioprine inhibits the *de novo* and salvage pathways for purine biosynthesis. MMF inhibits the *de novo* synthesis of guanine nucleotides. Because activated lymphocytes use the *de novo* pathway predominantly, MMF is thought to have greater selectivity than azathioprine. Corticosteroids inhibit lymphocyte proliferation by inhibiting macrophage production of cytokines, including IL-1 and IL-6.

The drugs in these regimens act synergistically, permitting dosage reduction when used in combination. This helps minimize dosage-dependent toxicity to the transplant recipient. Cyclosporine can cause nephrotoxicity, neurotoxicity, hypertension, hyperlipidemia,

BOX 98-5 Immunosuppression Regimen for Heart Transplant Recipients

PERIOPERATIVELY

- Corticosteroid—methylprednisolone (125 mg IV, every 8 hours for three doses, starting 8 hours after the induction dose in the operating room)

POSTOPERATIVELY

Induction Therapy

- rATG (1 mg/kg, with a maximum of 125 mg, over 6 hours daily for 3 days; premedication with diphenhydramine and acetaminophen, addition of hydrocortisone premedication if timing does not coincide with prednisone or methylprednisolone)

Maintenance Therapy

- Prednisone (20 mg twice daily; taper to baseline dosage by 3 months after transplant)
- Tacrolimus (dosage according to level, with daily trough; beginning dosage, 0.5 mg daily; aim for whole blood level of 12-15 for normal renal function, 8-10 for mild renal insufficiency, 4-6 for severe renal insufficiency)
- Cellcept (1000 mg twice a day, ½ hour before or 2 hours after food)

Alternative Immunosuppressive Agents

- Azathioprine (2 mg/kg PO every night; decrease dosage by half if WBC < 5000 or in the presence of severe renal failure, then titrate for WBC count; hold dosage if WBC < 4000)
- Sirolimus (1 mg PO every day; target level, 5-7)

WBC, White blood cell count.

hirsutism, and gingival hyperplasia. Tacrolimus is also nephrotoxic and neurotoxic and has been associated with glucose intolerance and new-onset diabetes mellitus. Both cyclosporine and tacrolimus are metabolized by the liver and cause upregulation of the cytochrome P450 system. Azathioprine and MMF cause dosage-dependent bone marrow suppression. Corticosteroids are associated with myriad side effects, including poor wound healing, development of cushingoid features, hypertension, diabetes mellitus, osteoporosis, and peptic ulcer disease.

Rapamycin, or sirolimus, is an alternative immunosuppressive agent that has been used successfully in renal and liver transplantation.¹³³ It inhibits mTOR (mammalian target of rapamycin), thereby blocking IL-2 signaling pathways.^{132,134} Rapamycin also inhibits smooth muscle proliferation and has been used in drug-eluting coronary stents to inhibit neointimal hyperplasia. Experimental animal models have shown inhibition of cardiac allograft vasculopathy (CAV) with rapamycin treatment and this has been validated in small, single-institution studies.¹³⁵⁻¹³⁷ A randomized clinical trial performed by Keogh and associates in OHT recipients compared sirolimus with azathioprine in combination with cyclosporine and steroid immunosuppression. Those patients receiving sirolimus showed a significant decrease in acute rejection: 32.4% to 32.8% of sirolimus-treated patients versus 56.8% of azathioprine patients. Sirolimus appeared to also aid in the prevention of CAV at 6 months and up to 2 years.¹³⁸ Additionally, Topilsky and coworkers retrospectively reviewed patients transitioned from a calcineurin inhibitor-based immunosuppressive regimen to a sirolimus-based regimen. In their study, patients receiving sirolimus ended up having lower overall mortality and lower incidence of CAV-related events.¹³⁶

The role of mTOR inhibitors, including sirolimus and everolimus, in the immunosuppressive armamentarium for OHT recipients continues to be controversial, especially regarding calcineurin inhibitor withdrawal and sirolimus conversion in patients with renal impairment. Transition from calcineurin inhibitor to sirolimus in OHT recipients with significant renal dysfunction (requiring hemodialysis) has yielded beneficial results in terms of renal improvement and number of episodes of clinical rejection at 1 year.¹³⁹ On the other hand, evidence shows that mTOR inhibitors may be associated with an increase in wound healing complications. Conflicting data were summarized by a cardiac transplant multidisciplinary committee in 2008, which concluded that calcineurin inhibitor withdrawal in OHT recipients should not be instituted until after the first year of transplantation.¹⁴⁰

Despite the huge advancement of immunosuppressive drug therapy for cardiac transplantation, the specific combination of agents necessary for increased survival, safety profile, and decreased rejection has not been established. Transplant centers' immunosuppressive protocols vary widely, and most existing studies report only short-term findings. Taylor and colleagues¹⁴¹ performed a small prospective randomized multicenter study comparing the efficacy of tacrolimus-based immunosuppression with that of cyclosporine-based immunosuppression. At 1-year follow-up, rejection rates were comparable in both

groups, although the incidence of hypertension and hyperlipidemia was less in the tacrolimus group. A randomized multicenter trial comparing the triple drug regimens of cyclosporine–azathioprine–prednisone and cyclosporine–MMF–prednisone showed improved 1-year survival and greater freedom from rejection in the cyclosporine–MMF–prednisone group.¹⁴² A greater increase in herpes simplex viral infection was found in the cyclosporine–MMF–prednisone group compared with that in the cyclosporine–azathioprine–prednisone group (21% vs. 15%), but no difference in other infectious complications or malignancy was found. In 2006, Kobashigawa and coworkers¹⁴³ conducted a large multicenter randomized trial consisting of 343 OHT recipients who were randomized to receive steroids and either tacrolimus–sirolimus, tacrolimus–MMF, or cyclosporine–MMF. The primary endpoint was incidence of ISHLT grade 3A or greater rejection or hemodynamic compromise requiring therapy within the first 6 months. Secondary endpoints included patient and graft survival at 1 year, rejection incidence, and safety profile. ISHLT grade 3A rejection episodes were diminished in the tacrolimus–MMF group versus the cyclosporine–MMF group at 1 year (23% vs. 36%). At 35%, the tacrolimus–sirolimus group had the lowest incidence of treated rejection episodes of any of the groups. The incidence was 42% in the tacrolimus–MMF group and 59% in the cyclosporine–MMF group. The tacrolimus–MMF group had significantly lower mean serum creatinine compared with the tacrolimus–sirolimus and cyclosporine–MMF groups: 1.3 mg/dL versus 1.5 mg/dL. The triglyceride level (126 mg/dL versus 162 mg/dL in tacrolimus–MMF and 154 mg/dL in cyclosporine–MMF) was also better for the tacrolimus–MMF group. The authors concluded that the combination of steroids, tacrolimus, and MMF may be the most beneficial immunosuppressive regimen in OHT recipients because of fewer rejection episodes and improved side effect profiles.

Along with multidrug immunosuppression regimens, many centers use cytolytic induction therapy to rapidly deplete lymphocytes in heart transplant recipients. This therapy occurs over a 3- to 10-day course, beginning immediately after transplantation. Induction immunosuppressive therapy has declined in popularity to the point that only 47% of heart transplant recipients received it in early 2012.² Currently available induction agents include the following: IL-2 receptor antagonists, such as daclizumab and basiliximab,^{144,145} which are humanized antibodies that effect the destruction of activated T cells expressing the IL-2 receptor on their cell surface; polyclonal antilymphocytic antibodies, for example, antithymocyte globulin (ATG), which is a rabbit or equine polyclonal antibody preparation that results in rapid cytolytic depletion of T cells; and alemtuzumab, a monoclonal antibody directed at CD52.¹⁴⁶ Induction therapy has advantages and disadvantages. Because immunosuppression is immediate, maintenance immunosuppression with other drugs can be delayed. In cases of hemodynamic instability or questionable renal function, this can be advantageous. Initial doses of ATG may be associated with a “cytokine release syndrome,” which manifests with fever, chills, hypotension, and bronchospasm. Patients

receiving this induction agent should be premedicated with acetaminophen, antihistamines, and corticosteroids and should be monitored closely. Because these preparations are raised in animals, patients may develop neutralizing antibodies, making prolonged and repeated courses impossible. Induction therapy with ATG may decrease the incidence of acute rejection in some cases, but in others, it simply delays the time of onset to rejection. Both are associated with a higher incidence of infectious complications and posttransplant lymphoproliferative disorder.¹³² Of note, OKT3 (muromonab-CD3), a mouse monoclonal antibody targeting the CD3 receptor on activated T cells, is no longer available because of a higher incidence of posttransplantation lymphoproliferative disease and side effect profile with no demonstrable benefit over other antibodies.^{147,148}

The experience with IL-2 receptor blockade is more limited, but 1-year follow-up studies have shown a decrease in the frequency and severity of acute rejection and a decrease in development of CAV.^{149,150} Kobashigawa and colleagues¹⁵¹ investigated the safety profile of daclizumab with patients on triple drug therapy consisting of cyclosporine–MMF–steroids from the Scientific Registry of Transplant Recipients. They demonstrated that daclizumab-induced patients had no increased risk for death or infectious death when compared with no induction therapy. Daclizumab-treated recipients also experienced lower rates of acute rejection at 6 and 12 months, with an overall 23% reduction when compared with non-induced patients.

A Cochrane review revealed that IL-2R antagonists were associated with lower incidence of acute rejection compared with no induction therapy. However, polyclonal antibody induction may be associated with a reduced incidence of biopsy-proven severe acute rejection compared with IL-2R antagonists.¹⁵² Long-term prospective studies are needed to determine whether induction with IL-2 receptor antagonists provides a survival benefit and to define patient populations that would benefit most from these therapies.

COMPLICATIONS

Hyperacute Rejection

Hyperacute rejection is a form of humorally mediated rejection. Preformed antibodies in the recipient recognize donor vascular endothelial antigens, resulting in activation of inflammatory and coagulation cascades. Graft vessels thrombose resulting in graft loss. ABO matching of donor and recipient has decreased the rate of hyperacute rejection. For recipients with an elevated PRA, prospective crossmatching of donor lymphocytes with recipient serum has also decreased the rate of hyperacute rejection.

Acute Rejection

The risk for acute rejection is highest during the first few months after transplantation and then persists at a low constant level. Most heart transplant patients experience

at least one episode of acute rejection, and there is a small mortality risk associated with each of these episodes. According to ISHLT data, acute rejection is the cause of death in approximately 11% of patients between 1 and 3 years after transplantation.² In 1994, the Cardiac Transplant Research Database group identified risk factors for recurrent rejection after heart transplantation.¹⁵³ In the first year after transplantation, these risk factors include shorter interval since previous rejection episode, young age, female sex, female donor, positive cytomegalovirus serology, prior infections, and OKT3 induction. After the first year, the dominant risk factors are a greater number of rejection episodes during the first year and the presence of prior cytomegalovirus infections.

The clinical presentation of acute rejection varies widely. Patients may be asymptomatic or may have non-specific clinical signs and symptoms, including fever, anorexia, leukocytosis, and mild hypotension. In rare cases, acute rejection manifests with severe hypotension and circulatory collapse. Because these clinical signs and symptoms lack a high degree of sensitivity or specificity in the diagnosis of acute rejection, the gold standard diagnostic test is a tissue biopsy. Percutaneous endomyocardial biopsy is performed as a part of routine surveillance protocols after heart transplantation. A bioprobe is passed through a sheath in the right internal jugular vein and advanced through the tricuspid valve into the right ventricle, where tissue biopsies are taken. Clinicians should be well versed in tissue sampling, because tricuspid regurgitation, although rare, is a recognized complication. Pathologically, acute rejection can be a focal patchy process, so four to six biopsies should be taken to reduce sampling error.¹⁵⁴ A typical surveillance endomyocardial biopsy protocol includes weekly biopsies for the first 4 weeks after transplantation, biweekly biopsies for the next month, and then monthly biopsies through the sixth month after transplantation. If the patient is free from rejection at 6 months, the frequency of biopsies is reduced to every 3 months.

Because of the cost, invasive nature, and potential for complications associated with endomyocardial biopsy, investigators are now developing alternative noninvasive techniques to monitor cardiac allograft rejection.¹⁵⁵ Emerging and promising techniques include magnetic resonance imaging,¹⁵⁶ wall motion analysis with tissue Doppler imaging,¹⁵⁷ electrical event monitoring with ventricular evoked response amplitude assessment,¹⁵⁸ identification of peripheral blood markers of rejection (e.g., P-selectin, prothrombin fragments, B-type natriuretic peptides, troponin),^{159,160} imaging for necrosis with antimyosin antibody-based scintigraphy,¹⁶¹ and imaging for apoptosis with technetium 99m-labeled annexin V.¹⁶²

Acute Cellular Rejection

The primary process leading to acute rejection is acute cellular rejection, which is T cell mediated. Donor antigen presenting cells (APCs) may be directly recognized by recipient T cells, or donor antigens may cross into the recipient to be taken up by recipient APCs.¹⁶³ The presentation of antigens to T cells via APCs causes conformational changes in the T cell receptor. In the presence of a

TABLE 98-3 ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection*

Grade	Criteria
Grade 0R [†]	No rejection
Grade 1R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage
Grade 2R, moderate	Two or more foci of infiltrate with associated myocyte damage
Grade 3R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema ± hemorrhage ± vasculitis

*The presence or absence of acute antibody-mediated rejection (AMR) may be recorded as AMR 0 or AMR 1, as required.

[†]R denotes revised grade, to avoid confusion with 1990 scheme. ISHLT, International Society for Heart and Lung Transplantation. From Stewart S, Winters GL, Fishbein MC, et al: *Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection*. *J Heart Lung Transplant* 24(11):1710–1720, 2005.

costimulatory molecule, i.e., B7 (CD80 or CD86), on the APC interacting with CD28 on the T cell, promotion of T cell proliferation and cytokine production occurs.¹⁶⁴ Following the sensitization of effector cells, there is a migration of lymphocytes into the allograft with subsequent activation of either the FAS-FAS ligand or perforin/granulysin pathway resulting in myocyte death.¹⁶⁵

A standardized grading system for cardiac acute rejection was developed by the ISHLT Heart Rejection Study Group in 1990. This system graded acute rejection with a score of 0 to 4, with 0 being no rejection and 4 being severe acute rejection. However, with the advent of newer, more effective immunosuppressive regimens and better understanding of transplant immunobiology, a revision of the previous Working Formulation, focused mainly on grade 2 cellular rejection, was approved by the ISHLT board in December 2004.¹⁶⁶ Table 98-3 illustrates this revised ISHLT standardized cardiac biopsy grading system of acute cellular rejection. Briefly, 1990 ISHLT grades 1A, 1B, and 2 combined into 2004 ISHLT grade 1R; 1990 ISHLT grade 3A is now 2004 ISHLT grade 2R; and 1990 ISHLT grades 3B and 4 became 2004 ISHLT grade 3R.

Treatment of Acute Cellular Rejection

When a histologic diagnosis of rejection is made, treatment consists of augmentation of immunosuppression. The degree of augmentation depends on the grade of rejection in addition to symptomatic status (Fig. 98-4). Asymptomatic patients with low grade rejection detected on surveillance biopsy may be managed with adjustments in the patient's regimen, titration to drug levels, and follow-up biopsy. Patients with moderate to severe acute cellular rejection should be treated aggressively even in the absence of symptoms or graft dysfunction.¹²⁹ In the symptomatic patient, prompt institution of therapy is critical independent of the grade of rejection. Options for acute therapy include corticosteroids or ATG.

Modifications to a patient's long-term immunosuppressive regimen may include substituting tacrolimus for

cyclosporine. Similarly, sirolimus or MMF may be substituted for azathioprine. If rejection does not respond to this treatment, an additional pulse of steroids may be given. Acute rejection is rarely refractory to these measures. In such cases, total lymphoid irradiation,¹⁶⁷ plasmapheresis,¹⁶⁸ and conversion of azathioprine to cyclophosphamide or methotrexate have been used.¹⁶⁹

Antibody-Mediated Rejection

Antibody-mediated rejection (AMR), which is a process mediated by donor-specific antibodies (DSAs), has emerged as a major cause of allograft loss. This has led to intense study of evaluation, diagnosis, and treatment. Patients with AMR are more susceptible to developing CAV, and they have a significant mortality rate (17%) in the early posttransplant period.¹⁷⁰ Long-term survival was decreased in recipients with a diagnosis of AMR. Taylor and coworkers¹⁷¹ found that in patients with AMR, allograft 3-year survival was 57%, and the risk for graft loss and dysfunction was approximately twice that in recipients with cellular rejection only.

Acute AMR is estimated to occur in 15% of cardiac recipients. Both the presence of acute AMR and cellular rejection were reported in 23% of biopsy specimens from 587 cardiac recipients. AMR manifests clinically as early as 2 to 7 days if the recipient has been presensitized with donor HLA, or as late as 1 month after transplant, and it may be associated with a rise in DSAs.¹⁷¹ For patients experiencing early AMR, approximately 70% develop allograft dysfunction.¹⁷² If AMR occurs late—several months to years—graft dysfunction is much less common, at 13%.

Generally, the incidence of AMR is increased in transplant recipients with prior sensitization to HLA antigens.¹⁷³ This is not limited to HLA; there is a growing body of evidence that non-HLA autoantibodies may also contribute to AMR.^{174,175} Patients with PRA greater than 10% are at increased risk of AMR.¹⁷⁶ With the increasing number of cardiac retransplants and patients receiving LVAD, the proportion of potential recipients who are sensitized and on the waiting list is expanding. The causes of preformed antibodies are transfusion, previous transplantation, and pregnancy, with pregnancy being a major cause of allosensitization in women.

The development of de novo antibodies occurs in a large proportion of patients,¹⁷⁷ up to 35% in one report with associated decrease in 5-year survival. However, not all autoantibodies will inflict allograft injury. In a process known as “accommodation,” patients may continue to have normal function in the presence of circulating antibodies against donor antigens.

In 2004, the ISHLT assembled an updated version of the grading system for AMR—the Revision of the 1990 Working Formulation for the Standardization of Nomenclature in the Diagnosis of Heart Rejection.¹⁶⁶ In these guidelines, allograft dysfunction and presence of DSAs were requisite criteria for diagnosis of AMR. Wu and colleagues found that patients with asymptomatic AMR developed CAV with greater frequency than did matched controls, suggesting that outcome may be affected in the absence of allograft dysfunction.¹⁷⁸ Moreover, patients

FIGURE 98-4 ■ Treatment algorithm for acute rejection in heart transplant recipients. Ab, Antibody; AZA, azathioprine; MTX, methotrexate.

with asymptomatic AMR may be at greater risk for cardiovascular mortality than cellular rejection.¹⁷⁹ Based on this evidence, a consensus conference on AMR was convened in 2010 with the recommendation that the diagnosis be based on histopathology and immunopathology rather than relying on clinical presentation and serologic studies. In 2013, the ISHLT published a statement standardizing the diagnosis of AMR incorporating the recommendations from the 2010 consensus conference¹⁷⁶ (Table 98-4).

Treatment of Antibody-Mediated Rejection

Although the exact treatment regimens for recipients with AMR vary between transplant centers, the principles on which it is based are the same: aggressive hemodynamic management along with augmentation of the immunosuppressive regimen to maximize the effort against circulating DSAs and lessen B cell activity. Plasmapheresis, steroid therapy, rituximab, ATG, bortezomib, and IVIG are used in a variety of combinations.¹⁷⁶ Figure 98-5 shows a proposed algorithm for the treatment of AMR in cardiac recipients.

Infection

An inherent complication of immunosuppression is increased risk for infection. In the first three years after transplantation, infection is the cause of death in 12% to

29% of patients.² The pathogens involved vary depending on the time after transplantation. Early infections in the first month after transplantation are commonly caused by bacteria and often manifest as pneumonia or urinary tract infections.¹⁸⁰ Typical pathogens include *Pseudomonas aeruginosa*, *Escherichia coli*, and *Staphylococcus aureus*. Whereas infectious episodes are decreasing in frequency overall, the proportion of infections caused by gram-positive organisms is increasing.¹⁸¹ The use of perioperative antibiotics and early removal of invasive catheters may aid in the prevention of perioperative infections. Late infections are typically caused by opportunistic pathogens, fungi, and viruses. However, the risk of infection decreases over time as immunosuppressive therapy is generally tapered.¹⁸² The proportion of mortality attributable to infection is only 11% to 12% greater than 3 years out from heart transplantation.²

Cytomegalovirus (CMV) is the most common and clinically significant viral pathogen in heart transplant recipients.¹⁸³ It may cause a variety of syndromes and has been implicated as a trigger for accelerated CAV. Heart transplant recipients are at high risk for CMV infection because cell-mediated immunity, which is necessary to combat CMV, is impaired by conventional immunosuppressive drugs. CMV infection may manifest either as primary infection or as reactivation of a latent infection. Primary CMV infection may develop in seronegative recipients receiving a heart from a CMV seropositive donor. In such cases, donor leukocytes or the allograft itself may harbor CMV and transmit it to the recipient.

TABLE 98-4 ISHLT Standardized Cardiac Biopsy Grading: Acute Antibody-Mediated Rejection (AMR)

Grade	Definition	Substrates
pAMR 0	Negative for pathologic AMR	Histologic and immunopathologic studies are both negative.
pAMR 1 (H+)	Histopathologic AMR alone	Histologic findings are present and immunopathologic findings are negative.
pAMR 1 (I+)	Immunopathologic AMR alone	Histologic findings are negative and immunopathologic findings are positive (CD68+ and/or C4d+).
pAMR 2	Pathologic AMR	Histologic and immunopathologic findings are both present.
pAMR 3	Severe pathologic AMR	Interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis, and/or karyorrhexis, and marked edema and immunopathologic findings are present. These cases may be associated with profound hemodynamic dysfunction and poor clinical outcomes.

Reactivation of latent CMV may occur in seropositive recipients. The risk for CMV infection in different populations of cardiac transplant recipients is illustrated in Table 98-5. The seronegative recipient of a heart from a seropositive donor and those being treated for acute rejection with antilymphocyte antibody preparations are at highest risk.

CMV infection can manifest as a mononucleosis-like syndrome, or it may be tissue invasive. The most common sites for tissue invasion are the lung, liver, and gastrointestinal tract. Less common sites include the retina and skin. Diagnosis is made by measurement of viral load with either quantitative polymerase chain reaction or

antigenemia assays; by direct culture of the virus from blood, urine, or tissue specimens; or by observation of characteristic histologic changes (enlarged cells containing nuclear inclusion bodies). A combination of intravenous ganciclovir and hyperimmune globulin is used to treat CMV infection.¹⁸³

Several populations of cardiac transplant patients benefit from prophylactic treatment against CMV infection. Serologically mismatched patients (seronegative recipient of heart from seropositive donor) are treated with a combination of ganciclovir and hyperimmune globulin for weeks to months after transplantation.^{183,184} Often, seropositive recipients are also treated with a

TABLE 98-5 Risk of Cytomegalovirus (CMV) Disease in Populations of Cardiac Transplant Recipients

Donor CMV Serotype Status	Recipient CMV Serotype Status	Antilymphocyte Antibody Therapy	Incidence of Disease (%)
Positive	Negative	—	50-75
Positive or negative	Positive	No	10-15
Positive or negative	Positive	Induction	≈25
		Antirejection	50-75
Negative	Negative	—	≈0*

*In donor negative/recipient negative transplants, CMV disease is uncommonly seen under two circumstances: transfusion of viable leukocyte containing blood products from a seropositive donor or acquisition of virus in the community through intimate person-to-person contact.

From Rubin RH: Prevention and treatment of cytomegalovirus disease in heart transplant patients. *J Heart Lung Transplant* 19(8):731–735, 2000.

course of ganciclovir to prevent reactivation infection. Some groups have shown that administration of intravenous ganciclovir when antilymphocyte antibody therapy is used to treat rejection reduces the risk for CMV disease to baseline levels.

Protozoal pathogens that can appear after heart transplantation include *Pneumocystis carinii* and *Toxoplasma gondii*. Pulmonary infection with *P. carinii* can be prevented by routine postoperative prophylaxis with trimethoprim sulfamethoxazole or aerosolized pentamidine (for sulfa-allergic patients). Toxoplasmosis may occur in serologically mismatched patients (e.g., *T. gondii*-seronegative recipient of heart from *T. gondii*-seropositive donor) but may be prevented by prophylaxis with atovaquone.^{181,185}

Invasive fungal infections are uncommon after cardiac transplantation, but when they occur, they cause significant morbidity and mortality. Fungal pathogens include *Candida albicans* and *Aspergillus*. Treatment consists of fluconazole, itraconazole, or amphotericin B.

Cardiac Allograft Vasculopathy

The long-term success of cardiac transplantation is limited to some extent by the development of CAV. The mechanism of injury leading to CAV is poorly described. The recipient immune response to the donor heart results in endothelial injury mediated by recipient APCs and direct recognition of donor MHC.^{163,186,187} The process of T cell activation produces a cascade of events that increases leukocyte adhesion to vessel walls and stimulates vascular remodeling.⁵⁰ The end result is the development of intimal fibromuscular hyperplasia, atherosclerosis, or vasculitis, which results in a histopathologic appearance similar to atherosclerotic disease in the nontransplanted patient.⁴³ However, CAV differs from atherosclerosis in extent and tempo. The disease process results in diffuse concentric narrowing of both epicardial and intramyocardial vessels. In addition, disease can appear within weeks of transplantation in spite of rigorous screening for coronary disease.¹⁸⁸

Analyzing data in the Cardiac Transplant Research Database, Costanzo and colleagues reported that at 5 years, angiographically evident CAV was present in 42% of transplant patients with 7% having severe disease. Risk factors for the development of CAV in this study included

older donor age,¹⁸⁹ donor history of hypertension, donor male sex, recipient male sex, and recipient black race.¹⁹⁰ Additional risks include recipient factors such as post-transplantation hyperlipidemia, hypertension, and diabetes, and donor factors including explosive method of death and intracranial hemorrhage.^{191,192} Aziz and coworkers stratified the incidence of CAV by underlying patient diagnosis and correlated a primary diagnosis of ischemic cardiomyopathy with an increased incidence of CAV.²⁶

Significant CAV results in diminished coronary artery blood flow and may lead to arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive heart failure. It is unusual for patients with severe CAV to have classic anginal symptoms, because the cardiac graft is denervated. Between 10% and 12% of late deaths after heart transplantation are attributable to CAV.² Because of the significant morbidity and mortality associated with CAV, screening for CAV occurs at most transplant programs. Yearly coronary angiography is recommended, although it lacks sensitivity and typically underestimates the presence of disease. Dobutamine stress echocardiography also may be used for routine screening.¹⁹³ Intracoronary ultrasound, when available, is a more sensitive procedure that provides information about intimal area, lumen area, and plaque morphology.^{194,195}

Treatment for CAV is limited. Because of the diffuse nature of the disease, patients are rarely candidates for coronary artery bypass grafting. Focal stenoses have been treated with angioplasty and stenting, but there is a high rate of restenosis.¹⁹⁶ Ultimately, severe progressive disease may require retransplantation. Because treatment options are limited, prevention of CAV is essential. Risk factor modification, including control of hyperlipidemia, hypertension, and hyperglycemia, may limit development of the disease. At-risk patients should receive routine prophylaxis against CMV.

Neoplasm

The incidence of neoplasia is higher in transplant recipients than in the general population. This is undoubtedly a consequence of chronic immunosuppression. Moreover, because immunosuppressive regimens are particularly aggressive in thoracic organ transplantation, these patients develop malignancies more often than renal and

liver transplant recipients.¹⁹⁷ The ISHLT reports that between 28% and 32% of heart transplant recipients develop malignancies by the tenth year after transplantation.^{1,2} Of these, most are skin cancers (squamous cell carcinoma and basal cell carcinoma)¹⁹⁸ and B cell lymphoproliferative disorders. B cell lymphoproliferative disorders cause the greatest degree of morbidity and mortality. They represent a spectrum of diseases ranging from cellular hyperplasia to true lymphomas, and more than 95% are associated with Epstein-Barr virus infection.¹⁹⁷ The mainstay of treatment for posttransplant lymphoproliferative disorder is reduction of immunosuppression and antiviral therapy.¹⁹⁹ Chemotherapy, radiotherapy, and immunotherapy have been used successfully in some cases. Other malignancies that occur at higher frequency in the transplant population include Kaposi sarcoma, carcinoma in situ of the cervix, and carcinoma of the vulva and anus. The incidence of solid organ tumors common in the general population (i.e., carcinoma of the lung, breast, colon and rectum, and prostate) is not higher in the transplant population.²⁰⁰

LONG-TERM RESULTS IN HEART TRANSPLANTATION

Long-term outcomes in heart transplantation have improved considerably in the past several decades, and median survival for all patients since 1982 is now 11 years (Fig. 98-6). Risk factors for 1-year mortality reported in the 2013 ISHLT registry include preoperative temporary circulatory support, chronic device therapy, total artificial heart, dialysis dependence, previous transfusions, gender mismatch, ventilator dependence prior to transplantation, and diagnosis.² Additionally, low preoperative albumin,²⁰¹ renal insufficiency not requiring dialysis,³¹ race, heart failure causes,²⁰² and poor preoperative clinical status may contribute to poor postoperative outcomes.²⁰³ Aside from recipient factors, annual heart transplant center volume has been shown to affect 30-day and 1-year mortality.²⁰⁴ Rather than a strict reflection of procedural success, annual volume appears to be a proxy for the aggregate of human factors and health systems.

Significant risk factors for late mortality include both pretransplantation recipient and posttransplanta-

tion characteristics. Elevated PRA, HLA mismatch, ventilator dependence, temporary circulatory support,² recipient age younger than 55 years, recipient history of diabetes, and race all contributed to late mortality, suggesting that recipient selection continues to be a key component in the determination of posttransplantation survival.²⁰⁵ After transplantation, an increasing burden of rejection episodes and more frequent infectious complications affect longevity.²⁰⁶ Annual heart transplant center volume has been an area of increasing interest. Increasing transplant center volume confers a protective effect on survival at 1, 5, and 15 years post transplantation. Performing nine or more transplants per year has been shown to be a significant inflection point for the determination of long-term success.²⁰⁵

Approximately 40% of patients are hospitalized in the first year after transplant, often for treatment of rejection or infection. By the second year after transplant, only 20% are hospitalized. The vast majority, approximately 90%, report good functional status after transplantation as reflected by a Karnofsky score of 80% to 100%. However, only 35% of working-age (25 years to 60 years old) heart transplant recipients were working at 1 year and 46% at 3 years after transplantation.²

SUMMARY

The history of heart transplantation is a remarkable one. Its development has exemplified the paradigm of surgical translational research that drives so many new therapies today. It remains the gold standard for surgical treatment of late-stage heart failure, even in the presence of emerging and exciting technologies. Although heart transplantation is still limited by the number of donor hearts available, liberalization of donor selection criteria as well as novel methods of preservation and resuscitation of donor hearts will likely increase the donor pool. Continued improvement in developing immunosuppressive therapies as well as postoperative care is decreasing mortality, complications, and hospital length of stay. The surgical principles that define the operative course of heart transplantation will likely remain the same as future possibilities such as stem cell-derived hearts appear.

PHYSIOLOGY OF THE TRANSPLANTED LUNG

LATE RESULTS

FUTURE DEVELOPMENTS

The clinical realization of heart–lung transplantation evolved through much earlier experimental developments in the laboratory. Alexis Carrel¹ (Fig. 99-1) and later Demikhov² and Marcus and associates³ performed experiments that explored the possibility of using heart–lung transplantation to replace diseased organs. When heart transplantation was first performed in 1968, Cooley, Lillehei, and Barnard all performed human heart–lung transplants, but patient survival time was short. Progress in the laboratory translated to the clinical application of the first successful human heart–lung transplant performed at Stanford in 1981.⁴ Since the time that these initial clinical transplantations were performed, combined heart–lung transplantation and isolated lung transplantation have undergone dramatic changes in all aspects, including indications, operative technique, and postoperative management. This chapter reviews the state-of-the-art and current issues in the field of heart–lung transplantation.

INDICATIONS FOR HEART–LUNG TRANSPLANTATION

Over time, with the increased technical success of isolated single- (SLT) or double-lung transplantation (DLT), the indications for combined heart–lung transplantation have narrowed. The primary reason for heart–lung

transplantation is irreversible dysfunction of both organ systems. The primary underlying defect could be cardiac in origin, such as congenital heart disease with irreversible end-stage cardiomyopathy and secondary pulmonary hypertension—also known as *Eisenmenger syndrome*. Alternatively, the primary defect could be pulmonary dysfunction, leading to irreversible heart disease over time. In general, the cardiac dysfunction is severe right-sided heart failure secondary to chronically elevated pulmonary arterial pressure—or *cor pulmonale*.

Another group of patients who have combined heart and lung disease has two separate disease processes that may not be related, such as a patient with a heavy smoking history who has severe emphysema and end-stage ischemic cardiomyopathy. These patients are rarely considered for heart–lung transplantation. However, experience with patients who have separate disease processes in the lungs and the heart has suggested that combined heart–lung transplantation is not a good treatment option and is associated with poor postoperative results and diminished long-term survival rates.

Recipient Diagnosis

The diagnostic profile of heart–lung transplant recipients reported to the Registry of the International Society for Heart and Lung Transplantation (ISHLT) from 1990 through 2007 is depicted in Figure 99-2.⁵ Pulmonary

hypertension secondary to congenital heart disease is the most frequent diagnosis, found in 33.9% of individuals who require heart–lung transplantation.⁵ Cardiac lesions that can result in secondary pulmonary hypertension include atrial and ventricular septal defects, patent ductus arteriosus, truncus arteriosus, and other complex congenital anomalies, including univentricular heart

FIGURE 99-1 ■ Alexis Carrel described the first heart–lung transplantation in a feline model in 1907. This experiment and numerous other observations predicted the eventual benefit of organ transplantation. For these outstanding accomplishments, Carrel received the Nobel Prize in 1912.

with pulmonary atresia and hypoplastic left heart syndrome. Pulmonary hypertension secondary to congenital heart disease varies prognostically when compared with primary pulmonary hypertension (PPH). Despite comparable levels of pulmonary arterial pressures, individuals with Eisenmenger syndrome have lower right atrial pressures, a better cardiac index, and an overall better prognosis than patients with pulmonary hypertension without congenital heart disease.⁶ Therefore, hemodynamic variables are less reliable in this group as an indicator for transplantation than is the presence of progressive symptoms (discussed later). Significant hemodynamic derangements in patients may be effectively managed with medical therapy, thus delaying transplantation.

Secondary pulmonary hypertension with complex, irreparable cardiac defects must be treated with heart–lung transplantation. In a recent study, patients with Eisenmenger syndrome caused by a ventricular septal defect or multiple congenital anomalies had a highly significant survival advantage when a heart–lung transplantation was performed as opposed to cardiac repair combined with lung transplantation.⁷ However, patients with simple cardiac defects, such as atrial septal defects, should be considered for repair of the cardiac defect combined with single or bilateral lung transplantation. Lung transplantation with intracardiac repair has evolved as a viable alternative to heart–lung transplantation for several reasons. First, right ventricular function improves after lung transplantation as a result of the normalization of pulmonary vascular resistance.⁸ In addition, there is a shortage of donor hearts. Furthermore, denervation and graft coronary artery disease associated with cardiac transplantation is avoided.

Primary pulmonary hypertension associated with irreversible right ventricular failure is the second most

FIGURE 99-2 ■ Indications for heart–lung transplantation from 1990 to 2005. AT def, Antitrypsin deficiency; COPD, chronic obstructive pulmonary disease. (Modified from Trulock EP, Christie JD, Edwards LB, et al: The Registry of the International Society of Heart and Lung Transplantation: Twenty-Fourth Official Adult Lung and Heart-Lung Transplant Report—2007. *J Heart Lung Transplant* 26:782–795, 2007.)

common indication for heart-lung transplantation, with 24% of recipients having this diagnosis.⁵ In contrast to secondary pulmonary hypertension from congenital heart disease, abnormal hemodynamic parameters are closely related to increased mortality.⁹ Therefore, patients with PPH should be promptly referred to a transplant pulmonologist for initiation of intravenous (IV) pulmonary vasodilators. If severe right ventricular failure persists despite aggressive medical therapy, heart-lung transplantation may be indicated.

The role of heart-lung transplantation in the setting of PPH has also evolved over the past several years. Individuals with pulmonary vascular disease and improved right ventricular function after initiation of medical therapy may also be treated effectively with either SLT or DLT. In the setting of PPH, DLT results in both greater hemodynamic improvement and a shorter duration of postoperative mechanical ventilation than does SLT,¹⁰ and it is the preferred operation in most transplantation centers. Furthermore, comparable survival rates were noted in patients with PPH after heart-lung transplantation and after DLT.¹¹ Because DLT decreases the use of scarce donor hearts, a trend has recently emerged in favor of DLT for patients with PPH. This trend has resulted in a decrease in the number of heart-lung transplants for PPH during the past 10 years. The subsets of patients who have fixed pulmonary vascular resistance that is not responsive to vasodilators, and who have irreversible right-sided heart dysfunction, are still candidates for heart-lung transplantation.

The remainder of heart-lung transplantations are performed for a variety of disorders that result in end-stage pulmonary failure and irreversible cardiac failure. These include individuals with septic lung disease, such as cystic fibrosis and bronchiectasis; ischemic and restrictive cardiomyopathies with intercurrent end-stage lung disease; or acquired pulmonary vascular disease. Primary parenchymal lung disease, such as idiopathic pulmonary fibrosis, desquamative interstitial pneumonitis, and lymphangioleiomyomatosis, may occur with severe right-sided heart failure and may also be a reason for heart-lung transplantation.

The introduction of the "domino" transplantation procedure renewed interest in heart-lung transplantation for septic lung disease. In this procedure, the recipient of a heart-lung transplant served as a heart donor for a second recipient, thus maintaining donor organ allocation.^{12,13} Recent studies have demonstrated equivalent survival rates in recipients of domino heart grafts and in recipients of cadaveric heart grafts. However, this procedure is rarely performed, and bilateral lung transplantation remains the procedure of choice for most septic or parenchymal lung disease.

The distribution of preoperative diagnoses managed with heart-lung transplantation at Stanford from 1981 to the present has been as follows: Eisenmenger syndrome, 44%; PPH, 23%; cystic fibrosis, 12%; complex congenital heart disease, 12%; α_1 -antitrypsin deficiency, 2%; cardiomyopathy with pulmonary hypertension, 2%; failure of SLT, 1%; congenital bronchiectasis, less than 1%; pulmonary lymphangioleiomyomatosis, less than 1%; and other diagnoses, 3%.¹⁴

Recipient Selection Criteria

The selection of appropriate candidates for heart-lung transplantation is of paramount importance for success of the procedure. Any patient with end-stage cardiopulmonary disease with the capacity for full rehabilitation is a potential candidate for heart-lung transplantation. Suitable candidates should have a life expectancy of less than 2 years and generally have marked persistent functional disability, with a New York Heart Association (NYHA) class designation of III or IV. Patients must otherwise be in good general health without other serious systemic illness. The occurrence of life-threatening complications, such as severe right-sided congestive heart failure with liver dysfunction, massive hemoptysis, or multiple syncopal episodes, suggests a poor prognosis and the need to list a patient as a candidate for heart-lung transplantation.

Recipients of heart-lung transplants generally are younger than heart transplant recipients, with 44% being between the ages of 35 and 49 years, and only 15% being older than 60 years.⁵ It must be determined that the patient and the family are emotionally prepared for transplantation. Each patient must be assessed for the presence of adequate emotional and psychosocial support to withstand the rigorous and intrusive medical regimen that will continue throughout their remaining life. Heart-lung transplantation has become more common as a therapeutic option for complex congenital heart disease in infants and children.^{15,16} These recipients also must be carefully evaluated, and they should have an extremely strong family support network to cope with the complex regimen and the frequent medical follow-up.

The risk for mortality while a patient is on the waitlist must be balanced with the 1-year mortality risk after transplantation to determine the ideal time to activate someone on the transplant waitlist. The individual's disease process should be severe enough to warrant heart-lung transplantation, yet the patient must be well enough to survive the long wait until the transplantation occurs, and well enough to survive the surgical procedure itself.¹⁷ The underlying disease determines the appropriate window. Survival with or without transplantation varies by disease process and by the patient's overall physical condition. Identification of a critical turning point in a patient's disease that signals an accelerated decline is the key to appropriate referral for transplantation. Pulmonary and cardiac clinical signs that can be used to gauge the appropriateness of listing include changes in the rate of decline in exercise capacity or pulmonary function, increasing frequency of infectious complications, increasing number and duration of hospitalizations, and increasing supplemental oxygen requirements. Other signs include increasing requirements for diuretics and increased hepatomegaly and bilirubin levels. Hyperbilirubinemia has been shown to be a marker for poor postoperative outcome in patients with pulmonary hypertension and right ventricular dysfunction. Patients with chronic bilirubin levels greater than 2.1 mg/dL who are undergoing heart-lung transplantation have been demonstrated to have significantly worse postoperative mortality (58%).¹⁸ The rate of perioperative complications,

including coagulopathy, hepatic encephalopathy, poor wound healing, and impaired clearance of cyclosporine with resultant nephrotoxicity, were also significantly increased after heart–lung transplantation in such patients.¹⁹

Heart–lung transplantation should be undertaken before multisystem organ failure and severe malnutrition ensue. Although patients await a suitable donor, many become increasingly debilitated. Every opportunity to optimize a patient's physical strength and nutritional status should be aggressively pursued.²⁰ Good physical performance before transplantation has been associated with improved postoperative recovery. Therefore, patients should be referred for physical therapy early in an effort to improve their functional status and optimize their recovery potential.

In the past, most centers considered conditions associated with extensive adhesions, such as previous thoracotomy or sternotomy, septic lung disease, and previous chemical or surgical pleurodesis, an absolute contraindication to heart–lung transplantation. Historically, patients with these conditions had increased morbidity and short-term mortality resulting primarily from excessive blood loss and pulmonary issues associated with massive transfusions of blood products. The introduction of antifibrinolytic therapy (aprotinin) in thoracic organ transplantation has provided improved outcomes for this group of patients.²¹ However, with increasing evidence that this drug is associated with worse survival and a higher risk for renal and neurologic complications after isolated coronary artery bypass surgery, its use in North American surgical programs has diminished markedly. Heart–lung transplantation in patients with previous surgery may remain one indication for its continued use.²² Current alternative antifibrinolytic options include aminocaproic acid and tranexamic acid. We now routinely accept patients with previous cardiac or thoracic surgery for heart–lung transplantation, and they represent a significant proportion of patients on the current waiting list.

In patients selected for transplantation, routine pretransplantation screening is performed for ABO blood group, the presence of preformed antibodies, human leukocyte antigen (HLA) and reaction of degeneration tissue types, and titers of antibodies against cytomegalovirus, herpes simplex virus, and toxoplasmosis. ABO compatibilities are strictly adhered to because isolated episodes of hyperacute rejection have been observed in patients in which transplantations were performed across ABO barriers. In addition to ABO compatibility, donor–recipient matching is also based on body size. In practice, matching donor and recipient height seems to be the most reproducible method for selecting the appropriate donor lung size. In general, the dimensions of the donor lungs should not be greater than 4 cm greater than those in the recipient. Other investigators have proposed that the simplest method of matching donor-to-recipient lung size is to use the respective predicted total lung capacity values.^{23,24}

Once an appropriate donor–recipient match is made, the recipient is screened for preformed antibodies against a panel of 50 random donors. A percent reactive antibody (PRA) level greater than 25% prompts a prospective

specific crossmatch between the donor and recipient. A positive crossmatch indicates the presence of anti-donor circulating antibodies in the recipient, and the organ cannot be accepted for transplantation. Despite several retrospective studies that reveal improved graft survival with HLA matching,^{25–27} prospective HLA matching is not feasible given the short ischemic times tolerated. Furthermore, in a recent multicenter study, HLA matching for lung transplantation did not have a large effect on clinical outcome, including the development of obliterative bronchiolitis (OB).²⁸

Recent data suggest that the presence of an elevated PRA level is associated with both early and late mortality.²⁹ In addition, elevated PRA levels have been shown to be associated with an increased incidence of acute rejection in both lung and heart transplantation patients, with an increased incidence of graft vascular disease in heart transplantation patients, and with an increased occurrence of accelerated bronchiolitis in lung transplantation patients.^{30,31} Methods to decrease the patient's PRA level and to avoid antibody production by virtual, or, when time allows, prospective crossmatching, have decreased the negative effects of high baseline PRA levels on late survival.³²

Many heart–lung transplant patients, especially in the pediatric population, have undergone previous cardiac surgery and are extremely sensitized when they present for heart–lung transplantation. Specific protocols using immunoglobulin, plasmapheresis, and rituximab have been shown to decrease the PRA levels in potential organ recipients. In addition, posttransplant treatment initiated in the operating room with plasma exchange, plasmapheresis, weekly immunoglobulin injections, and monitoring for the development of donor-specific antibodies has minimized the risk for hyperacute rejection in this population.³³ The current desensitization protocol being used at Stanford is shown in [Box 99-1](#).

TREATMENT OF PATIENTS AWAITING TRANSPLANTATION

The average waiting period for a heart–lung block is greater than 18 months; therefore, treatment of recipients after they have been listed is a critical aspect of the preoperative plan. Routine medical care, including clinical surveillance, optimization of cardiopulmonary function, and management of disease-specific and age-specific issues, should be addressed during this time. General considerations in the pretransplantation period include appropriate surveillance protocols and screening for malignancies such as prostate, breast, and colon cancer. Other issues that should be addressed include appropriate prophylaxis for thromboembolism with warfarin³⁴ and aggressive maximization of bone density, because osteoporosis is increasingly recognized as a clinical problem for patients who are receiving long-term steroid therapy.³⁵ Nutrition and high-intensity pulmonary rehabilitation should be optimized. Finally, psychosocial issues need to be addressed with referral for supportive counseling, support groups, and other training means to help each patient cope with the upcoming challenges.

BOX 99-1 Treating the Highly Sensitized Heart-Lung Transplant Patient

WEEK 1

- IVIG $\times$ 2 consecutive days; each dose, 1 g/kg at 100 mL/hr

WEEK 2

- Rituximab, 375 mg/m² IV

WEEK 3

- Rituximab, 375 mg/m² IV

WEEK 4

- IVIG $\times$ 2 consecutive days; each dose, 1 g/kg dose at 100 mL/hr
- Monthly IVIG treatment thereafter until transplantation

TRANSPLANT MANAGEMENT

- PRA level > 50% and complement fixation (C1q) absent:
 - Plasmapheresis in the operating room when patient is on cardiopulmonary bypass
 - Immediate retrospective crossmatch
- PRA level > 50% and complement fixation (C1q) present:
 - Prospective crossmatch before transplantation

IV, Intravenously; IVIG, intravenous immune globulin; PRA, percent reactive antibody.

Disease-specific issues in patients awaiting heart-lung transplantation need to be addressed. These patients require optimal treatment of heart failure with standard therapeutic measures such as sodium restriction, aggressive diuresis, and vasodilators. Afterload reduction with nitrates, hydralazine, and angiotensin-converting enzyme inhibitors prolongs survival in patients awaiting transplantation.³⁶ In patients with PPH, supplemental oxygen is recommended to avoid hypoxic pulmonary vasoconstriction. Indications for outpatient oxygen therapy include an arterial partial pressure of oxygen (Pao₂) of 55 mm Hg or less (or arterial oxygen saturation [Sao₂] < 88% on room air) at rest, during physical exertion, or while asleep.³⁷ The prognosis of patients with PPH is determined by hemodynamic variables, and the following parameters are associated with a poor outcome: increased mean pulmonary artery pressure (mPAP > 85 mm Hg; median survival, 12 months), increased mean right atrial pressure (RAP > 20 mm Hg; median survival, 1 month), and decreased cardiac index (CI < 2.0 L/min/m²; median survival, 17 months).⁹ In addition to supplemental oxygen therapy, initiation of pulmonary vasodilator therapy improves hemodynamics and survival in patients awaiting transplantation. Epoprostenol is a short-acting prostaglandin, normally released by the endothelium, that vasodilates the pulmonary vascular bed and inhibits platelet aggregation. Continuous infusion of epoprostenol (Flolan; GlaxoSmithKline, London, UK) has been demonstrated to significantly improve pulmonary hemodynamics, exercise capacity, and survival in patients with NYHA classes III and IV heart failure.^{38,39} Patients may

BOX 99-2 Heart-Lung Donor Selection Criteria

- Age <40 years
- Smoking history <20 pack-years
- Arterial PO₂ of 140 mm Hg on an FiO₂ of 40%, or 350 mm Hg on an FiO₂ of 100%
- Normal chest radiograph
- Sputum free of bacteria, fungus, or significant numbers of white blood cells on Gram and fungal staining
- Bronchoscopy showing absence of purulent secretions or signs of aspiration
- Absence of thoracic trauma
- Human immunodeficiency virus (HIV)–negative status

then wait longer for transplantation. Despite improvements in pulmonary hemodynamics and survival, diseases often progress or tachyphylaxis develops. Therefore, patients need to be followed closely and returned to the active transplant list if any clinical deterioration is noted. In patients who have right ventricular failure while awaiting transplantation, the creation of an interatrial shunt to decompress the pressure-overloaded ventricle may need to be considered.⁴⁰

Patients with cystic fibrosis awaiting heart-lung transplantation have special needs. Pulmonary hygiene is of critical importance, because greater than 80% of patients are chronically colonized with *Pseudomonas aeruginosa*.⁴¹ Pulmonary clearance techniques, institution of bronchodilators, and initiation of antibiotics in the setting of acute infection are lifelong requirements. Prophylactic antibiotics are not routinely given because of the development of multiresistant organisms.⁴² Sinus disease and lower respiratory tract infections are risks in most patients with cystic fibrosis. Bilateral maxillary sinus anastomies performed in the pretransplantation period have resulted in fewer infectious complications in the posttransplant period.⁴³ In addition to infectious issues, other associated risk factors such as malnutrition secondary to malabsorption, pancreatic insufficiency, and diabetes mellitus must be properly addressed.

SELECTION AND MANAGEMENT OF DONORS

The satisfactory criteria for heart-lung blocks are similar to those for hearts and lungs separately (Box 99-2). The lungs are the most delicate solid organ, with frequent parenchymal damage and neurogenic edema occurring after brain death, as well as the increased risk for aspiration. These factors result in only 20% to 30% of multi-organ donors having lungs suitable for donation. Preliminary donor evaluation includes a detailed history, review of electrocardiogram and echocardiogram, chest radiograph, and arterial blood gas analysis. A donor age of less than 40 years is preferred. However, potential donors aged 40 to 50 years are considered at most transplant centers, provided they have normal cardiopulmonary functioning and a normal coronary arteriogram. Acceptance criteria also include no significant lung

contusion or history of aspiration or sepsis. There should be no history of prior cardiac or pulmonary surgery. A donor chest radiograph must be clear with no signs of pathology. An arterial blood gas analysis should reveal an arterial oxygen tension level of greater than 350 mm Hg on a fractional inspired oxygen concentration (FiO_2) of 100%, and 100 mm Hg on an FiO_2 of 30%. Lung compliance is estimated by measuring peak inspiratory pressures, which should not exceed 30 cm H_2O . Tracheobronchial infection must be excluded with chest radiography, Gram stain of sputum, and bronchoscopy.

On arrival at the donor hospital, the retrieval team assesses the chest radiograph, recent arterial blood gas analyses, and hemodynamic parameters to confirm that there has been no deterioration in oxygenation or cardiac function. If possible, the bronchoscopic examination is repeated to ensure that there are no mucopurulent secretions suggestive of infection or aspiration, as in tracheobronchitis. The final assessment includes visual and manual intraoperative assessment of the heart and lungs, confirming normal lung parenchyma with no palpable masses or evidence of contusion.

Because of growing waiting lists and increased mortality before a transplant is received, most centers have expanded their donor acceptance criteria with the increased use of so-called marginal donors.⁴⁴ Thoracic trauma with a resultant pneumothorax is not a contraindication, provided there is not a continuous air leak. Furthermore, lungs that are mildly contused can also be used, provided ongoing bleeding is not noted on bronchoscopy and/or there is no major atelectasis. Patients with prolonged intubation and ventilation (>70 hours), once thought to be a contraindication, should also be considered. As noted previously, older donors also are being considered, provided that pulmonary functional parameters are normal and no significant coronary artery disease is detected. Donor infection with hepatitis C virus is an evolving area in cardiopulmonary transplantation. Hepatitis C–negative recipients have an increased risk for acquiring hepatitis, but the effect on patient survival remains unclear.⁴⁵ Absolute contraindications include severe coronary or structural heart disease, prolonged cardiac arrest, active malignancy (sometimes excluding primary brain cancers such as astrocytoma and skin cancers), smoking history of greater than five pack-years, and positive human immunodeficiency virus (HIV) status.

Donor management after a declaration of brain death is a critical area in which there are opportunities for significantly improving the number and quality of potential donors. Aggressive management strategies implemented by organ procurement organizations have made “unacceptable” lungs, defined as a Pao_2 -to- FiO_2 ratio of less than 150, acceptable for transplant.⁴⁶ Donors with unacceptable lungs were treated with invasive monitoring, methylprednisolone, fluid restriction, inotropic agents, bronchoscopy, and diuresis. The resultant “acceptable” organs were successfully transplanted without compromise of either 30-day or 1-year graft survival.⁴⁶ The major goal in the initial management of these donors is the maintenance of hemodynamic stability and pulmonary function. Patients who have suffered an acute brain injury are usually hypovolemic, and appropriate fluid

resuscitation is the initial step. Complicating factors include the development of diabetes insipidus, which should be treated with a vasopressin infusion (0.1 to 0.4 U/hr).⁴⁷ Fluid administration is guided by the central venous pressure, keeping in mind that a central venous pressure greater than 8 mm Hg has been demonstrated to be an independent risk factor for the development of lung dysfunction.⁴⁸ Inotropic agents such as dopamine or phenylephrine are instituted to maintain perfusion pressure after intravascular volume has been repleted. The donor is not hyperventilated after brain death is declared, and a pH of 7.40 is the goal, thus avoiding pulmonary vasoconstriction. Positive end-expiratory pressure of 5 is maintained to prevent atelectasis, and higher levels are avoided because of their deleterious effect on cardiac output.

The pathophysiology of brain death and its deleterious effect on the cardiovascular system have been well described.⁴⁹ The resultant endocrine and metabolic derangements are a potential area of intervention in the marginal donor with hemodynamic instability. Hormonal therapy, including triiodothyronine (T_3), cortisol, insulin, and vasopressin, has been shown to have beneficial effects on the hemodynamic profile of marginal donors.⁵⁰ Physiologic resuscitation, guided by a better understanding of the pathophysiology of brain death, ultimately leads to an increase in the number and quality of heart–lung donors.

HEART–LUNG PRESERVATION

The goal of optimal heart–lung preservation is to ameliorate the effect of ischemia–reperfusion (IR) injury on the allograft. In early heart–lung transplantations, donor transportation to the transplant center with on-site procurement was considered essential because of a lack of confidence in lung-preservation techniques. As with heart transplantation, better preservation techniques would expand the pool of available donors and would make donation more acceptable to referring hospitals and donors’ families.

Minimization of IR injury ultimately results in optimization of allograft function in the posttransplantation period. Nonspecific graft failure, which most likely represents IR injury, remains a significant cause of perioperative morbidity and possibly mortality.⁵¹ Reperfusion injury may predispose the transplant recipient to an increased risk for acute rejection secondary to the upregulation of histocompatibility class II antigens.⁵² Understanding the pathophysiology of IR injury allows the implementation of strategies aimed at preserving function, minimizing injury, and prolonging allograft and patient survival.

The result of inadequate preservation is activation of the inflammatory cascade, resulting in pulmonary endothelial injury and increased capillary permeability. The resulting pulmonary interstitial and alveolar edema leads to diminished airway compliance, poor gas exchange, and increased pulmonary vascular resistance. Numerous recent studies have elucidated the role of the neutrophil and its interaction with the pulmonary endothelium in

the pathogenesis of IR injury.⁵³⁻⁵⁵ Reperfusion injury is caused in part by a complex interplay between leukocyte activation and the subsequent release of inflammatory mediators and cytokines, which leads to pulmonary endothelial injury.

Since the early 1980s, various methods have been developed to provide adequate heart-lung preservation. These methods have varied from simple graft excision and cold storage to sophisticated autoperfusion with donor blood and a working heart-lung preparation. Today, only two methods are actively used: (1) perfusion with pulmonoplegia solutions and cold storage and (2) perfusion with cold donor blood. Both methods include the use of pulmonary vasodilators. Pulmonary artery flush, the most widely adopted method of allograft preservation,⁵⁶ allows the rapid cooling of both lungs, resulting in a significant improvement in allograft function noted after both the infusion time (4 minutes) and total volume (60 mL/kg) are increased.⁵⁷ To counteract the reflex pulmonary vasoconstriction arising from preservation solutions, donors are pretreated with prostaglandins. These selective pulmonary vasodilators, alprostadil in North America and epoprostenol in Europe, improve the distribution of the pulmonary arterial flush and thus improve lung preservation. Recently, the role of retrograde flush through the left atrium has been advanced because of the improved distribution of the flush in a porcine model.^{58,59}

The two types of crystalloid pulmonary artery flush solutions, intracellular and extracellular, are both designed to counteract the cellular swelling that results from graft ischemia and hypothermia. The intracellular solutions, Euro-Collins (EC) and University of Wisconsin, are composed of electrolytes that mimic the intracellular environment. The extracellular solutions include the Wallwork solution, which uses donor blood, and low-potassium dextran (Perfadex; XVIVO Perfusion AB, Gothenburg, Sweden). The most commonly used preservation solution is EC crystalloid solution, which has been modified with magnesium sulfate and 50% dextrose. A recent study has demonstrated that lung procurement with low-potassium dextran resulted in a significantly decreased incidence and severity of reperfusion injury with improved allograft function, as well as improved survival, when compared with EC.⁶⁰ The addition of a retrograde flush for isolated lung transplantation has resulted in improved posttransplant lung function.⁶¹ This retrograde flush technique can be safely used in combined heart-lung transplantation by making a small left atrial incision, flushing the preservation solution retrograde via the veins, and collecting the effluent in the proximal pulmonary artery, where a separate small incision is made. In contrast, the use of Celsior solution as a lung-preservation solution resulted in lethal posttransplant outcomes in a porcine model of lung transplantation.⁶²

Recent investigations in the laboratory and clinic have demonstrated improvements in allograft preservation after the modification of pulmonary arterial flush solutions. The focus has been to intervene at the level of the leukocyte-endothelial interaction in an effort to preserve the function of the pulmonary endothelial cell. The

impact of toxic inflammatory mediators elaborated by the leukocyte has been reduced by techniques such as leukocyte filtration,⁶³ introduction of monoclonal antibodies directed against anti-intercellular adhesion molecules and selectins,^{53,55,64} and vascular immunotargeting strategies.⁵⁴ Furthermore, treatments aimed at preserving pulmonary endothelial function by restoring endothelium-derived mediators, such as nitric oxide (NO) and prostacyclin, have been shown to improve allograft pulmonary function.⁶⁵⁻⁶⁸ Instead of focusing on the preservation solutions or additives, others have focused their attention on the development of continuous organ perfusion systems. The TransMedics Organ Care System is an organ perfusion system that preserves organs by using a warm-blood perfusion of the organ during storage. The system has been approved for use in Europe for donor heart procurement and in late-stage clinical trial protocols in the United States.

OPERATIVE TECHNIQUE FOR DONOR HEART-LUNG REMOVAL

In the early days of heart-lung transplantation, the donor was transported to the recipient hospital, and in an adjacent operating room, the recipient heart-lung block was excised simultaneously with donor organ preparation. Long-distance procurement is now the rule as a result of improvements in donor selection, donor management, and preservation techniques. Numerous procurement teams work together, and optimal communication is essential.

The donor operation is performed via a median sternotomy (Fig. 99-3). The pericardium is opened vertically and laterally on the diaphragm, and a pericardial cradle is created. Both pleural spaces are then opened, followed by the inspection of both lungs and pleural spaces. In cases of trauma, cardiac and pulmonary contusions are immediately ruled out. The pulmonary ligaments are then divided inferiorly by using electrocautery. The ascending aorta and aortic arch are dissected free and encircled with tapes. The superior and inferior venae cavae are then dissected free and also encircled with tapes. The azygos and innominate veins are ligated and divided, which affords excellent exposure to the proximal trachea. The tissue overlying the proximal trachea is incised vertically and encircled with a tape. Dissection of the distal trachea is kept to a minimum to avoid injury to the peribronchial vessels at the carina.

The patient is administered 300 U/kg of IV heparin, and the aorta and pulmonary artery are cannulated. Approximately 15 minutes before applying the aortic crossclamp, prostaglandin E₁ (PGE₁) is infused IV, initially at a rate of 20 ng/kg per minute and gradually increasing to a target rate of 100 ng/kg per minute. During PGE₁ infusion, the mean arterial blood pressure should be maintained at greater than 55 mm Hg. Inflow occlusion is accomplished by ligating the superior vena cava distally to avoid damage to the sinoatrial node. The inferior vena cava is clamped with a straight Potts clamp. The heart is allowed to empty, and the aortic crossclamp is applied. Cold crystalloid cardioplegia (10 mL/kg) is

FIGURE 99-3 ■ The donor operation. **A**, Through a median sternotomy, adhesions are lysed and the pulmonary ligaments are divided inferiorly. **B**, The pericardium is opened and cradled, followed by dissection of the ascending aorta, venae cavae, pulmonary artery, and trachea. **C**, Tapes are placed around the aorta, venae cavae, and trachea. **D**, The entire anterior pericardium is excised back to each hilum. **E**, Cardioplegia and pulmonoplegia solutions are infused simultaneously into the aorta and main pulmonary artery after aortic crossclamping. Application of topical cold Physiosol follows immediately. **F**, The venae cavae and aorta are divided, and the heart–lung block is dissected free from the esophagus and posterior hilar attachments. After the trachea is stapled and divided at the highest point possible, the entire heart–lung block is removed from the chest. (From Yuh DD, Robbins RC, Reitz BA: Transplantation of the heart and lungs. In Edmunds LH, editor: *Cardiac Surgery in the Adult*, New York, 1997, McGraw-Hill, pp 1451–1475.)

administered via the aortic root. The inferior vena cava is incised, and the left atrial appendage is amputated immediately after initiating the pulmonoplegia. Adequate venting should be ensured and cardiac distention avoided. Pulmonoplegia with an EC solution at 4°C is rapidly infused at a rate of 15 mL/kg per minute for 4 minutes. During the administration of cold cardioplegia and pulmonary perfusate, copious amounts of cold topical saline are immediately poured over the heart and lungs. The lungs are ventilated with half-normal tidal volumes of room air while the dissection is completed, separating the heart–lung block from the posterior mediastinum, from inferior to superior. The lungs are inflated to a tidal volume of three-fourths normal, and the trachea is stapled with a TA-55 stapler and divided. The aorta is then divided, and the heart–lung block is removed, wrapped with sterile towels, and immersed in ice-cold saline at 4°C in preparation for transport (see Fig. 99-3).

Clinically, we have used grafts preserved for up to 6 hours with successful implantation and outcome.

OPERATIVE PROCEDURE

The operation to replace the heart and lungs is one of the most fascinating and challenging procedures for cardiothoracic surgeons. The anatomy that is encountered and the areas of the thorax that are dissected are not otherwise commonly seen. Careful attention to details can simplify the procedure in even the most challenging patients.

Patients with PPH with end-stage right ventricular failure are usually the ideal candidates for heart–lung transplantation. These patients generally have not had previous cardiac or thoracic surgery and do not have large mediastinal collaterals from cyanosis. Conversely, patients

with congenital heart disease and pulmonary atresia, or Eisenmenger syndrome and cyanosis, may have large mediastinal bronchial collaterals that require careful ligation. The most challenging aspect of the procedure is to remove the heart and lungs without injury to the phrenic, recurrent laryngeal, and vagus nerves. Careful attention to hemostasis is necessary before implantation of the graft, because exposure of many of the areas of dissection is difficult.

The recipient procedure for heart-lung transplantation has evolved over the past decade, with two major changes often used: the conversion from atrial cuff to bicaval anastomoses, and the positioning of the pulmonary hila anterior to the phrenic nerve pedicle. The right atrial cuff anastomosis was initially proposed in heart-lung transplantation to facilitate cannulation for cardiopulmonary bypass and eliminate the possibility of stenoses at the vena caval anastomoses. As in the transplantation of the heart alone, asynchronous contraction of both atrial cuffs is associated with an increased incidence of atrioventricular valve regurgitation. A demonstrated clinical benefit of caval anastomosis is fewer postoperative arrhythmias.⁶⁹ Because the pulmonary hila are positioned anterior to the phrenic nerve pedicle, less posterior mediastinal dissection is required, resulting in decreased rates of phrenic and vagus nerve injury.⁷⁰ Another advantage to this technique is that it allows for easier inspection of the posterior mediastinum for bleeding by rotation of the heart-lung block anteriorly and medially while the patient is still on cardiopulmonary bypass.

With careful attention to detail in the posterior mediastinal dissection and during the creation of the windows in the pericardium, the placement of the lungs posterior to the phrenic nerves can be performed safely. The primary advantage to this approach is seen in the reoperation setting. The placement of the donor lungs posterior to the phrenic nerves results in maintenance of the normal anatomic relationships, which facilitates the dissection at the time of repeat transplantation.

The patient is prepared for operation with the usual monitoring lines. After the induction of general anesthesia, the chest and both groins are prepared and draped in a sterile manner. A standard median sternotomy incision is made, and both pleural spaces are opened anteriorly (Fig. 99-4). A portion of the pericardium is removed anteriorly, avoiding the phrenic nerves. The ascending aorta and both venae cavae are dissected free and encircled with tapes. After fully heparinizing the recipient, the high ascending aorta and both venae cavae are cannulated separately, cardiopulmonary bypass is instituted, and the patient is cooled to 28°C. The aorta is cross-clamped, and a small amount of cardioplegia may be given to induce cardiac arrest.

First, the heart is excised as in heart transplantation. Next, the lungs are removed sequentially. The right and left bronchi are skeletonized, and a stapling device (TA 30, 4.8 mm) is used to occlude them. Cutting the bronchus distally allows the lung to be removed easily and avoids contamination from the open bronchus.

The native main pulmonary artery remnant is then removed. A portion of the pulmonary artery is left intact adjacent to the underside of the aorta in the region of the

ligamentum arteriosum, which minimizes damage to the recurrent laryngeal nerve. The final step in preparing the recipient is to open the pericardium at the superior part of the pericardial space just anterior to the right and left bronchi, allowing dissection back to the carina. The stapled ends of the right and left bronchi are grasped, and dissection is carried up to the level of the distal trachea. In this area, it is important to stay directly on the bronchus, use electrocautery if possible, and avoid injury to the vagus nerve as it passes posterior to the bronchus and anterior to the esophagus. The vascular lymph nodes in this area may be very large, particularly in patients with cystic fibrosis. Bronchial vessels are individually identified and ligated or clipped. Patients with secondary pulmonary hypertension from congenital heart disease have large mediastinal bronchial collaterals that must be carefully ligated. Hemostasis is imperative in this area of dissection because exposure to this region is difficult after transplantation of the heart-lung block. The chest wall also is carefully inspected, and electrocautery or an argon beam coagulator is used. After absolute hemostasis is ensured, the donor heart-lung graft is prepared for implantation.

The donor heart-lung block is removed from its sterile container and brought to the operative field in a basin of cold saline solution. The donor trachea is excised several rings above the carina, and the superior tracheal segment, with the clamp attached, is then removed from the field. The tracheobronchial tree is aspirated with a sucker that is later discarded. At the same time, a sample to be cultured is taken directly from the trachea. The trachea is trimmed back so that only one complete cartilaginous ring is left just above the carina. A syringe full of normal saline is used to irrigate the bronchi and visualize them for retained secretions or any foreign body that might have been aspirated by the donor.

The heart-lung graft is then lowered into the chest with the lung hila anterior to the phrenic nerve pedicles (see Fig. 99-4). A cold saline solution and gauze pads soaked in cold saline are placed over the lung and heart to maintain hypothermia during implantation. The recipient trachea is opened one cartilaginous ring above the carina, and all the adventitial peritracheal tissue that is adjacent to the superior tracheal segment is left in place. Small bronchial vessels may require a Liga clip or suture; use of electrocautery at the cut edge of the trachea should be avoided. The tracheal anastomosis is performed with a running suture of 3-0 polypropylene, starting on the left side of the trachea and completing the posterior row from the inside. The same suture is continued anteriorly from outside the trachea. There should be a fairly close size match between donor and recipient, but any disparity can generally be accommodated by the flexible membranous part of the trachea. These bites usually go around at least one cartilaginous ring, and the donor trachea slightly invaginates the recipient trachea in most cases. When the tracheal anastomosis is complete, the chest is irrigated with several liters of ice-cold saline solution to cool the graft and to help remove any contamination from the trachea.

The recipient inferior vena cava is then anastomosed to the donor inferior vena cava by using a running 4-0

FIGURE 99-4 ■ The recipient operation. **A**, Through a median sternotomy, the anterior pericardium is partially removed, and the ascending aorta and both venae cavae are dissected and encircled with tapes. **B**, The right phrenic nerve is carefully separated from the right hilum. **C**, Cannulation for cardiopulmonary bypass consists of a cannula in the high ascending aorta and separate vena caval cannulas. Once the patient is on cardiopulmonary bypass, the native heart is excised in a manner similar to that used for standard cardiac transplantation. **D-E**, Left and right pneumonectomies are performed by dividing the respective inferior pulmonary ligament, pulmonary artery and veins, and main-stem bronchus. **F**, The heart-lung block is lowered into the chest, placing the hila anterior to each respective phrenic nerve pedicle. **G**, The tracheal anastomosis is performed with a continuous 3-0 polypropylene suture. **H**, The caval and aortic anastomoses are performed with a continuous 4-0 polypropylene suture. (From Yuh DD, Robbins RC, Reitz BA: Transplantation of the heart and lungs. In Edmunds LH, editor: *Cardiac Surgery in the Adult*, New York, 1997, McGraw-Hill, pp 1451–1475.)

polypropylene suture. At this point, the patient is rewarmed toward 37°C, and the superior vena caval and aortic anastomoses are performed in an end-to-end fashion by using a continuous 4-0 polypropylene suture (see Fig. 99-4). After completion of the aortic anastomosis, the patient is placed in a slightly head-down position, the ascending aorta and pulmonary artery are aspirated for air, and the caval tapes and the aortic crossclamp are removed. A leukocyte filter in the cardiopulmonary bypass circuit is opened 10 to 20 minutes before the aortic unclamping. The tracheal tube is aspirated by

using sterile technique, and ventilation is resumed with room air. The left atrial opening at the appendage is repaired. When the patient's body temperature is almost normal and heart and lung function are satisfactory, cardiopulmonary bypass is discontinued and decannulation is performed routinely. The inspired concentration of oxygen is increased as required. Temporary pacing wires are applied to the donor right atrium and ventricle and brought out through the skin below the incision. Right-angled chest tubes are placed in the right and left pleural spaces, and a straight chest tube is placed in the

mediastinum. Methylprednisolone (500 mg) is given to the recipient after heparin reversal with protamine sulfate.

The posterior mediastinum is then inspected for bleeding by carefully rotating the heart-lung block anteriorly and medially while the anesthesiologist uses hand ventilation. This maneuver is facilitated by using the most recent modification, in which the pulmonary hila are placed anterior to the phrenic nerves. Large amounts of warm saline solution at 37°C are used to irrigate both pleural spaces and the mediastinum. When hemostasis is satisfactory, the sternum is closed routinely with multiple stainless steel sternal wires.

POSTOPERATIVE MANAGEMENT

Intensive Care Unit

The immediate postoperative management of the patient undergoing heart-lung transplant is similar to that of any patient after cardiac surgery. Patients are allowed to awaken early in the postoperative course and are monitored closely for hemodynamic stability and bleeding. Endotracheal tube suctioning is performed when appropriate, and the patient is weaned from the ventilator in a routine manner. When the patient is alert and hemodynamically stable and blood gases and ventilatory mechanics are satisfactory, the patient is extubated. Strict attention is paid to fluid balance, and a vigorous diuresis is encouraged in most patients. As soon as possible, the patient is allowed to sit in a chair and begin ambulation. A physical therapist works with the patient to facilitate rapid rehabilitation.

Several points must be kept in mind when treating heart-lung transplant patients in the immediate postoperative period. Early graft dysfunction, manifested by progressive hypoxemia and hypercapnia, can be present in up to 10% to 15% of patients.⁵¹ The proposed etiology is IR injury in the transplanted lung. This injury results in increased pulmonary capillary permeability, alveolar edema, impaired pulmonary compliance, and increased pulmonary vascular resistance with right ventricular dysfunction. Graft dysfunction can progress rapidly, and early treatment is essential. Initiation of pulmonary vasodilators such as alprostadil or inhaled NO may be necessary. Inhaled NO has been demonstrated to decrease the intrapulmonary shunt, optimizing ventilation-perfusion matching after lung transplantation.⁷¹ In another study, inhaled NO administered in the setting of lung allograft dysfunction doubled the ratio of arterial oxygen tension to inspired oxygen fraction (P_{aO_2} to F_{iO_2}) within 1 hour of administration.⁵¹ Furthermore, significant reductions in airway complications, duration of mechanical ventilation, and mortality were noted.⁵¹ In cases of persistent, severe pulmonary graft dysfunction refractory to all intervention, extracorporeal membrane oxygenation has been used successfully to stabilize gas exchange in several patients.⁷²

Immunosuppression

The immunosuppression regimen for heart-lung transfer recipients includes induction therapy with polyclonal

TABLE 99-1 Early Induction Immunosuppressive Therapy after Heart-Lung Transplantation

Immunosuppressive Agent	Dosage
Methylprednisolone	500 mg IV after administration of protamine in the OR 125 mg IV every 8 hours for 3 doses
Rabbit antithymocyte globulin	1.5 mg/kg IV on POD 1, 2, 3, 5, and 7
Daclizumab	1 mg/kg (first dose in OR, then every 14 days on POD 14, 28, 42, and 56)

IV, Intravenously; OR, operating room; POD, postoperative days.

TABLE 99-2 Early Immunosuppression Therapy after Heart-Lung Transplantation

Immunosuppressive Agent	Dose
Tacrolimus	Start with 1 mg orally twice a day on POD 1
0-6 mo	12-15 ng/mL
7-12 mo	10-15 ng/mL
>12 mo	8-10 ng/mL
If sirolimus added	5-7 ng/mL
Mycophenolate mofetil	Start at 500 mg twice a day on POD 1; adjust to white cell count >4 and side effects
Prednisone	
Induction	Hold 8 days, then start at 0.6 mg/kg, divided doses
No induction	Start on POD 1 at 0.6 mg/kg, divided doses

POD, Postoperative day.

rabbit antithymocyte globulin (RATG) and maintenance therapy with tacrolimus, mycophenolate mofetil, and prednisone. Standard protocol is depicted in [Tables 99-1](#) and [99-2](#).

Induction therapy is used on the basis of data showing that it decreases the incidence of early acute rejection, chronic rejection, and OB.^{73,74} Induction therapy is initiated with RATG (1.5 mg/kg IV) on postoperative days (POD) 1, 2, 3, 5, and 7 (see [Table 99-1](#)). If the patient is hemodynamically unstable or allograft function is compromised from reperfusion injury, RATG dosing is delayed for several days. From 1987 to 1993, induction therapy at some centers was switched from RATG to OKT3, the murine monoclonal antibody directed specifically against the T cell (CD3) receptor. However, the use of OKT3 was later shown to be associated with a greater incidence of acute pulmonary allograft rejection, postoperative infection, and OB when compared with RATG.⁷⁵ These findings resulted in a return to using the polyclonal anti-T cell antibody for induction therapy. More recently, there has been a switch to using the interleukin (IL)-2 receptor blocker daclizumab for induction therapy, or to using no induction therapy, especially in patients with significant posttransplant IR injury.

Methylprednisolone (500 mg IV) is administered intraoperatively and continued postoperatively at a dose of 125 mg IV every 8 hours for three doses. If induction therapy is used, maintenance prednisone is withheld for 1 week. Steroids are then restarted on POD 8 with a daily divided oral dose of 0.6 mg/kg prednisone, which is gradually tapered over the next 3 to 4 weeks to 0.1 to 0.2 mg/kg per day. The risk for airway complications after transplantation is not adversely affected by the use of postoperative steroids.⁷⁶ If induction immunotherapy is not used, then prednisone is started after the IV dosing is completed at a dose of 0.6 mg/kg per day in divided doses, with gradual tapering down to a maintenance dosage of 0.1 mg/kg per day.

In addition to steroids, maintenance immunosuppressive therapy includes mycophenolate mofetil and tacrolimus. Mycophenolate mofetil is initiated on POD 1, starting at a dosage of 500 mg twice daily. The dosage is titrated to maintain a leukocyte count greater than 4000/mm³ and to avoid significant side effects. Tacrolimus is also initiated on POD 1 and titrated slowly based on trough levels, with the goal of achieving therapeutic levels on POD 5. This strategy avoids high serum levels and prevents nephrotoxicity. Patients who are unable to tolerate oral intake secondary to prolonged intubation or malabsorption are administered one third of the calculated total dosage IV in a continuous manner.

Although this immunosuppressive regimen has served heart–lung transplantation well, high rates of acute allograft rejection, infection, and chronic rejection, primarily manifested as OB, still exist. The quest for more efficacious and less toxic immunosuppressive regimens is a continual investigative challenge. Starting in approximately 2005, there was a shift from the use of cyclosporine to tacrolimus that was based on studies suggesting that the incidence of OB syndrome was lower with the use of tacrolimus.⁷⁷ Mycophenolate mofetil has been shown to have antiproliferative effects on T and B cells by inhibiting *de novo* purine biosynthesis, with improved efficacy and reduced toxicity.⁷⁸ An added advantage of using mycophenolate mofetil is the selective expansion of regulatory T cells, which may lead to better host tolerance of the transplanted organ.⁷⁹ In addition, newer T cell–inhibitory agents, such as sirolimus (rapamycin), which specifically blocks smooth muscle cell proliferation, can potentially prevent both acute rejection and the manifestations of chronic rejection, also with less toxic side effects.^{80,81}

COMPLICATIONS

Acute Rejection

The fine balance between adequate immunosuppression and the risk for infection and rejection remains one of the most difficult problems in heart–lung transplantation, as with any lung transplantation. The detection of acute rejection is rare in the first postoperative week, and the majority of episodes occur within the first year after transplantation. The diagnosis of acute rejection in the early posttransplantation period is usually based on

FIGURE 99-5 ■ Acute and resolving lung rejection. **A**, Chest radiograph illustrates bilateral infiltrates characteristic of acute pulmonary rejection. **B**, Follow-up chest radiograph after pulsed methylprednisolone treatment of acute rejection demonstrates resolution of infiltrates.

clinical parameters manifested by lung allograft dysfunction. Signs of acute rejection include dyspnea, low-grade fever, impaired oxygenation and ventilatory parameters (including a diminished forced expiratory volume in 1 second [FEV₁]), and diffuse interstitial infiltrates on chest radiograph (Fig. 99-5).⁸² Acute cellular rejection during the first month is associated with an infiltrate seen on the chest radiograph in 75% of cases. After the first month, however, the chest film is normal or without change in 80% of patients.^{83,84} The role of other modalities such as spirometry, computed tomography (CT), and bronchoscopy with transbronchial biopsy (TBB) become increasingly important.

Acute allograft rejection in the early postoperative period is the single most significant risk factor for the development of subsequent OB, so the role of surveillance modalities in detecting and treating early rejection become critical in preventing chronic rejection and improving survival rates. Spirometric surveillance has been shown to be a reasonable screening tool for acute rejection. FEV₁ and forced expiratory flow rate at 25% to 75% of vital capacity (FEF_{25%-75%}) were noted to

be decreased during episodes of acute rejection, with FEF_{25%-75%} being the best parameter to distinguish acute rejection from infection.⁸⁵ Because of some lack of sensitivity and specificity of spirometric surveillance, however, TBB remains the gold standard for the detection of rejection.

In heart-lung transplantation, the simultaneous rejection of both the heart and lung is rare,⁸⁶ and endomyocardial biopsy does not help diagnose acute lung rejection.⁸⁷ Furthermore, histologic assessment by using TBB is superior to cardiac biopsies because cardiac rejection is very rare without lung rejection, and thus the need for routine endomyocardial biopsies has been eliminated.⁸⁸ Surveillance bronchoscopy with TBB in heart-lung recipients is routinely performed at 2 and 4 weeks after transplantation, and then at 2, 3, 6, and 12 months thereafter, or as clinically indicated. At least five TBB specimens that contain lung parenchyma are necessary to obtain an adequate quantity of specimen. TBBs performed in the setting of clinical symptoms were positive for rejection or infection in 72% of cases.⁸⁶ The yield for surveillance biopsies after 1 year in asymptomatic patients, however, is very low.⁸⁹ Late postoperative biopsies are therefore guided by clinical parameters, and any deterioration in pulmonary function leads to further evaluation.

Rejection episodes occurring within the first 3 months, or those graded as moderate or severe, are treated with IV methylprednisolone at a dose of 1000 mg/day for 3 consecutive days, followed by an increased oral maintenance dose of 0.6 mg/kg per day, tapered to 0.2 mg/kg per day over 3 to 4 weeks. Both the chest radiograph appearance and clinical symptoms usually improve rapidly after the initiation of pulsed steroid therapy. In milder cases of rejection, or in cases occurring after 3 months, treatment consists of increased oral prednisone, followed by a gradually tapered dose over 3 to 4 weeks. Patients with steroid-resistant or persistent allograft rejection are treated with either monoclonal (OKT3) or polyclonal (RATG) antilymphocyte therapy. Other potential treatments in refractory and recurrent cases include switching to rapamycin, methotrexate, total lymphoid irradiation, or extracorporeal photochemotherapy.⁹⁰⁻⁹³

Infection

Infectious complications remain a significant cause of morbidity and mortality in heart-lung recipients. The spectrum of potential pathogens is extensive, yet some common patterns can be appreciated. Bacterial infections are most prevalent early in the postoperative period, with the highest incidence noted in the first month after heart-lung transplantation.⁹⁴ Bacterial infections can manifest as pneumonia, mediastinitis, line sepsis, urinary tract infections, and skin infections. Gram-negative bacilli are the most common bacterial pathogens. Late after transplant, opportunistic pathogens such as viral, fungal, and protozoal species are more common.

Cytomegalovirus (CMV) is the most common viral pathogen in heart-lung transplants. CMV has been associated with pneumonitis in as much as 50% of patients and is associated with an increased incidence of chronic

rejection manifested as accelerated graft coronary artery disease and OB.^{95,96} In addition to pneumonia, CMV infection can have presenting symptoms such as leukopenia and fever, gastroenteritis, hepatitis, and retinitis. CMV events occur within the first 12 months, with the majority appearing within the first 3 months. Individuals at the greatest risk for serious infections are seronegative recipients (R⁻) receiving a heart-lung block from a seropositive donor (D⁺). The incidence of serious infections in these patients is 90%, which falls to 10% when recipient and donor are CMV-negative. The diagnosis of CMV disease (symptomatic) or CMV infection (without symptoms) is established by several means: seroconversion from anti-CMV immunoglobulin M (IgM) negative to positive; a fourfold rise in CMV IgG antibody titers; positive viral cultures from urine, blood, or dimercaprol (bronchoalveolar lavage); or CMV inclusion bodies on transbronchial biopsy.

Most transplant centers perform transplants across CMV serologic barriers, implementing prophylactic measures in high-risk patients (D⁺R⁻). These patients receive prophylaxis with CMV hyperimmunoglobulin (CytoGam; CSL Behring, King of Prussia, PA) in addition to ganciclovir (DHPG).⁹⁷ This combination regimen resulted in a significant decrease in both CMV disease and CMV infection when compared with DHPG alone.⁹⁸ Standard protocol is to administer DHPG at 5 mg/kg IV twice per day for 14 days, then at 6 mg/kg once per day for 20 days. After DHPG, valganciclovir (Valcyte; Genentech, South San Francisco, CA) (900 mg) is initiated for 6 weeks after transplant. CytoGam is given at a dosage of 150 mg/kg IV within the first 72 hours after transplantation and then continued at a dosage of 100 mg/kg at 2, 4, 6, and 8 weeks, followed by 50 mg/kg at weeks 12 and 16 after transplant.

Fungal organisms are the least common pathogens, yet these infections are associated with the greatest mortality. The risk of fungal infections after lung, heart-lung, and heart transplantation can be significantly lowered by prophylaxis with aerosolized amphotericin B.⁹⁹ Inhaled treatments with amphotericin B have been shown to decrease the rate of fungal infections at 3 months from 0.8% to 0.2%, and the incidence fell twofold at 12 months when compared with a group that did not receive the inhaled treatment.⁹⁹ Bronchodilators are administered prophylactically before treatment to reduce bronchospasm. Fungal infections, diagnosed by sputum culture or CT-guided needle aspirate, are aggressively treated with intravenous amphotericin B administration.

Pneumocystis jiroveci pneumonia has been effectively prevented in heart-lung recipients since the initiation of prophylaxis with the combination of sulfamethoxazole and trimethoprim.¹⁰⁰ The dosages of sulfamethoxazole and trimethoprim are 800 mg and 160 mg, respectively, twice daily, 3 days per week, adjusting the dosage for renal insufficiency. If patients have a sulfur allergy or leukopenia develops, inhaled pentamidine (300 mg) is initiated once a month. *Toxoplasma gondii*-negative recipients receiving a transplant from a seropositive donor are treated with a 6-week course of pyrimethamine (25 mg) every day and leucovorin (10 mg) every day. In addition, long-term prophylaxis typically includes clotrimazole

(Mycelex Troches) for the prevention of mucosal candidal infections.

Chronic Rejection—Obliterative Bronchiolitis

The main cause of long-term morbidity and mortality after heart–lung transplantation is chronic rejection, primarily manifested as OB. The clinical diagnoses of bronchiolitis obliterans syndrome (BOS) and the pathologic diagnoses of OB were defined in the working formulation by the ISHLT.¹⁰¹ BOS does not require a histologic diagnosis; it is defined as a deterioration of graft function secondary to progressive airways disease. Other potential etiologies such as acute rejection and infection must be excluded before a diagnosis of BOS is reached. The clinical manifestations of BOS include a dry cough and progressive dyspnea. Interstitial pulmonary infiltrates are seen on the chest radiograph, and an obstructive pattern is seen in pulmonary function tests. BOS can be staged on the basis of the deterioration of FEV₁.¹⁰¹ OB, on the other hand, is a histologic diagnosis based on the presence of eosinophilic fibrous scarring of the membranous and respiratory bronchioles, with partial or complete obliteration of the lumen.¹⁰²

The overall incidence of BOS or OB at 5 years after heart–lung transplantation, as reported by the ISHLT Registry, is approximately 48% (Fig. 99-6).⁵ Significant risk factors associated with the development of OB include the frequency and severity of acute rejection, as well as the appearance of lymphocytic bronchiolitis on TBB.⁷³ Furthermore, organizing pneumonia, as well as CMV infection, significantly potentiates the effects of acute rejection.

A growing body of evidence supports the hypothesis that OB is an immunologically mediated process. In addition to its association with acute rejection, the disease is most commonly found in patients with the greatest degree of HLA mismatch.¹⁹ Patients with OB have an increased number of mismatched major histocompatibility complex (MHC) class II antigens,¹⁰³ immunologic mediators such as IL-2 and IL-6 in bronchioalveolar

lavage fluid,¹⁰⁴ and a predominance of CD8⁺ cytotoxic and suppressor cells on TBB.¹⁰⁵ CMV infection may have a stimulatory effect on the immune system that enhances the viral injury.¹⁰⁶ CMV prophylaxis with ganciclovir has been demonstrated to delay the onset of OB.¹⁰⁷ In addition to its immunologic stimulus, CMV also has a direct stimulatory effect on the smooth muscle cells of the airways, as well as indirectly via the elaboration of growth factors and mitogenic mediators.¹⁰⁸ Better control of the immune response, prevention of acute rejection, and reducing CMV infection are the best therapies for preventing the incidence of BOS or OB.

For long-term surveillance, patients are provided with a portable spirometer so that expiratory flow can be checked frequently between clinic visits.^{109,110} If there is any interval decrease or any signs of respiratory tract infection, the patient is instructed to contact the transplant center or primary care physician so that pulmonary function tests can be performed. Any subsequent alteration in FEV₁ 25%-75% prompts further evaluation with bronchoscopy and bronchoalveolar lavage, and TBB. After infection has been ruled out, augmentation of immunosuppression is the current mode of therapy. If acute rejection is seen with the TBB, pulsed-dose steroids are started (methylprednisolone, 1 g IV for 3 days). In the setting of augmented immunosuppression, CMV prophylaxis is begun, with ganciclovir and fungal prophylaxis combined with inhaled amphotericin B.

Despite stabilization of pulmonary function with augmented immunosuppression, relapse rates are greater than 50%, and mortality is significant.^{111,112} The actuarial survival curves for heart–lung transplant patients are quite different for patients with BOS/OB and those without BOS/OB (Fig. 99-7). Markedly better survival rates were also demonstrated in patients with BOS stage 1 than in those with BOS stages 2 or 3.¹¹¹ The main cause of death is usually respiratory failure secondary to a superimposed pneumonia. Retransplantation often remains the only therapeutic option, although the results of retransplantation in patients who have developed

end-stage OB are poor, with an actuarial survival rate of only 25% at 1 and 3 years after transplantation.¹¹³

Chronic Rejection—Graft Coronary Artery Disease

Very few heart-lung recipients who survive the first year will die as a result of graft coronary artery disease.^{114,115} The incidence of cardiac allograft rejection in heart-lung recipients is low.⁸⁷ The incidence of angiographically detectable coronary artery disease was only 11% at 5 years after heart-lung transplantation,¹¹⁴ which is similar to the data from the ISHLT Registry (see Fig. 99-6).⁵ This is in contrast to heart-only transplant recipients, of whom as many as 50% develop significant angiographic disease by 5 years; this is the major cause of mortality and retransplantation in these patients. A recent study using intracoronary ultrasonography confirmed the low incidence of transplant coronary artery disease in heart-lung recipients when compared with the heart-alone recipient group.¹¹⁶ When the lungs and heart are both transplanted, the lungs are more immunologically active. This observation was confirmed in an animal model, in which hearts that were transplanted in combination with lungs or spleen displayed an impressive reduction in myocardial rejection; this phenomenon is termed the *combi-effect*.¹¹⁷

Complications of Immunosuppression

There are several side effects resulting from long-term immunosuppression. Cyclosporine causes nephrotoxicity, hypertension, hepatotoxicity, hirsutism, and gingival hyperplasia, and it is associated with an increased incidence of lymphoma. Azathioprine causes a generalized bone marrow depression manifested as leukopenia, thrombocytopenia, and anemia. Long-term use of steroids causes hypertension, diabetes, osteoporosis, and impaired wound healing. Induction therapy with either RATG or OKT3 can cause significant hemodynamic instability and respiratory compromise manifested as fever, hypotension, and bronchospasm. Patients are therefore premedicated with corticosteroids, acetaminophen, and antihistamines before the administration of immunosuppressive agents.

One of the more troubling consequences of heart-lung transplantation is the development of posttransplant lymphoproliferative disorder (PTLD).¹¹⁸ This is characterized by lymphadenopathy and often a diffuse lymphocytic infiltrate on TBB.¹¹⁹ The treatment is immediate reduction in the intensity of the immunosuppression. The disease has essentially two forms: malignant and nonmalignant. Early onset of PTLD (<12 months after transplantation) is typically benign and resolves rapidly after reduced immunosuppression. Conversely, late PTLD is associated with a 70% to 80% mortality rate and typically resists reduction by immunotherapy or traditional chemotherapy.¹²⁰

Additional Complications

Airway complications have become rare after heart-lung and lung transplantation as the result of improvements

in surgical technique and postoperative management. The risk for a major airway complication after heart-lung transplantation is approximately half of that after a single-lung transplantation, with a reported incidence as low as 3.8%.¹²¹ The incidence of airway complications is unrelated to steroid use in the preoperative or postoperative period.⁷⁶ Furthermore, no significant correlation could be identified with the ischemic interval, anastomotic wrapping, or date of first rejection episode.¹²²

Abdominal complications after heart-lung transplantation remain a significant source of morbidity and mortality.¹²³ The prevalence of symptomatic gastroparesis after heart-lung transplantation is high, probably as a result of vagotomy at the time of removal of the heart-lung block.¹²⁴ Gastroparesis with gastric distention can lead to gastroesophageal reflux with subsequent aspiration. Episodes of aspiration and the resultant inflammatory response can result in significant lung allograft dysfunction. Furthermore, whether this allograft injury predisposes the patient to an increased risk for BOS or OB remains to be determined.¹²⁵ Laparoscopic antireflux surgery should also be considered in patients with severe reflux disease after heart-lung transplantation, because pulmonary function and reflux symptoms have been shown to significantly improve with this treatment.¹²⁶

PHYSIOLOGY OF THE TRANSPLANTED LUNG

Standard measure of pulmonary function indicates that long-term function of the transplanted heart and lungs is well maintained. Integrated cardiopulmonary function with exercise is also largely intact.^{127,128} Some debate has centered on a bronchial hyper-responsiveness to a methacholine challenge.¹²⁹ There does appear to be an associated decrease in mucociliary clearance, which may be a contributing factor to the serious and repeated infections seen in heart-lung recipients.¹³⁰ In the absence of OB and severe recurrent infection, the function of the transplanted heart and lungs is conducive to an excellent quality of life.¹²⁷

LATE RESULTS

A retrospective review of all 174 patients with end-stage cardiopulmonary disease who underwent heart-lung transplantation at Stanford University between the time of the first landmark operation in 1981 to 2000 revealed that 40% of these patients were still alive, with a 5-year actuarial survival rate of 49% (Fig. 99-8). This record compares closely with the worldwide experience with heart-lung transplantation, as reported by the ISHLT Registry, and is similar to that for patients receiving double-lung transplantation alone (Fig. 99-9).⁵ A review of the experience at Stanford from 1991 to 2002 reveals improved survival when compared with the preceding decade.¹⁴

Causes of mortality after heart-lung transplantation differ over time after surgery. Early deaths, occurring less than 1 month after surgery, are most often the result of

FIGURE 99-8 ■ Actuarial survival of patients who underwent heart-lung transplantation at Stanford University, 1981 to 2000.

FIGURE 99-9 ■ Heart-lung transplantation actuarial survival based on data from the International Society for Heart and Lung Transplantation (ISHLT) Registry. Half-life is time to 50% survival; conditional half-life is time to 50% survival of hospital survivors. (Modified from Trulock EP, Christie JD, Edwards LB, et al: The Registry of the International Society of Heart and Lung Transplantation: Twenty-Fourth Official Adult Lung and Heart-Lung Transplant Report—2007. *J Heart Lung Transplant* 26:782–795, 2007.)

infection (36% of overall deaths), hemorrhage (8% to 20%), acute respiratory disease syndrome (4%), and non-specific graft failure (7% to 9%).^{14,114} Acute rejection of the heart-lung graft is fairly uncommon, resulting in mortality in less than 2% of patients. Almost all rejection events in these patients occur within the first 3 months, with a linearized rejection rate twice as high for the lung (0.7 events per 100 days) when compared with the heart (0.35 events per 100 days). The most common cause of death after the immediate postoperative phase is OB. The overall prevalence of OB in patients surviving heart-lung transplantation longer than 3 months was 64%, with an overall mortality greater than 70% after 5 years of follow-up.¹¹¹ Additional causes of late death include infection, malignancy, and coronary artery disease. The incidence and severity of transplant coronary artery disease are significantly less when compared with those of the heart transplantation population.¹³¹ However, this complication remains an important cause of late death in heart-lung recipients.¹¹⁴

The long-term functional results after heart-lung transplantation are encouraging. Most recipients are able

to resume an active lifestyle without the need for supplemental oxygen, and they demonstrate significant increases in exercise capacity after transplantation.^{128,132} Pulmonary function as measured by spirometry is also markedly improved after heart-lung transplantation.¹²⁸ The functional benefits of heart-lung transplantation are particularly evident when considering that this subgroup of patients would otherwise have a life expectancy of less than 2 years, despite maximal medical and nontransplantation surgical therapy.

FUTURE DEVELOPMENTS

Imperfections remain in the use of heart-lung transplantation for definitive treatment of end-stage cardiopulmonary disease. Significant improvements in selective immunosuppression and the development of precise immunotolerance are required before heart-lung transplantation can restore normal heart and lung function without significant long-term morbidity and mortality. The development of new immunosuppressive agents, the use of genetic engineering to formulate new humanized monoclonal antibodies, and the field of pharmacogenomics provide continued hope for an improved outlook for heart-lung transplant recipients. Novel approaches such as ex vivo gene therapy, the induction of immunotolerance, and xenotransplantation are promising areas of continual investigation.

Coronary Artery Bypass Surgery with or without Surgical Ventricular Restoration: Insights into the STICH Trial
Mitral Repair

SUMMARY

In response to the increasing health, economic, and social impacts of heart failure, clinicians are investigating new surgical therapies that do not involve heart transplantation. Heart failure affects about 5 million patients in the United States, and more than 250,000 die annually. Nearly 70% of patients with heart failure have coronary artery disease, and nearly all have had a myocardial infarction (MI).¹ In part, the increase in the prevalence and incidence of heart failure results from improved diagnosis and treatment of cardiac disease (especially ischemic disease), but another factor is the aging of the population.² Despite improvements in medical treatment since the 1960s and the introduction of potent new drugs, the prognosis for patients affected by heart failure remains extremely poor.^{3,4} However, with recent advances in surgical therapy for cardiac disease, new surgical options can be offered to some of these patients as an alternative to medical therapy. Some conventional drug therapies have

not shown any significant improvement in the survival of patients with heart failure.⁵⁻⁸

After a diagnosis of heart failure, the 5-year mortality rate is still 60% for men and 45% for women, despite improvements in its medical management.⁹ Currently, improvements in surgery technology and in surgeons' skills have broadened the indications for cardiac surgery. Historically, patients with severe congestive heart failure (CHF) were listed for heart transplantation, and although this is a very effective therapy for end-stage heart failure, the limited number of donor organs remains a crucial problem.¹⁰ Indeed, the Registry of the International Society for Heart and Lung Transplantation shows that the number of heart transplant centers worldwide has dropped from 248 in 1995 to 201 in 2005.¹¹

Until recently, surgical management was directed toward the underlying pathology of coronary disease and the secondary mitral insufficiency that evolves as the

heart dilates, but surgeons do not systematically approach the ventricle. Surgical ventricular restoration (SVR), the topic of this chapter, was launched by Dor and colleagues¹² and represents a relatively novel surgical approach that aims to restore (i.e., bring back to normal) the dilated, distorted left ventricular (LV) cavity to improve function. It requires knowledge of the remodeling infrastructure, of the structural changes that lead to geometric abnormalities, and of the role of compensatory, remote muscle and stretching mechanisms that lead to electrical instabilities.¹³

SVR is more than a single procedure, because it includes coronary grafting and mitral repair when needed, and thus it has the potential to treat the three components of the disease: the ventricle, the vessels, and the valve ("triple V" as defined by Buckberg^{14,15}).

PATHOPHYSIOLOGY OF HEART FAILURE

Left Ventricular Remodeling

In dilated cardiomyopathy (a common cause of heart failure), a primary determinant of the disease process is LV remodeling. The underlying causes of dilated cardiomyopathy are diverse, and the origin may be nonischemic or ischemic.

LV remodeling is a complex, dynamic, and time-dependent phenomenon that involves molecular, cellular, interstitial, and genome-expression changes that manifest clinically as changes in the size, shape, and function of the heart after cardiac injury.¹⁶ The process can evolve slowly or rapidly after the myocardial injury, and it contributes importantly in the progression to end-stage CHF. Box 100-1 summarizes the principal changes that occur in LV remodeling. The extracellular matrix participates in the altered ventricular geometry after MI. Cardiologists and cardiac surgeons traditionally viewed the extracellular matrix as an inert collection of structural macromolecules that serve as a scaffold for cells. However, a large body of evidence supports a central role for the extracellular matrix in the control of numerous cellular functions¹⁷ and supports the idea that the extent of LV

remodeling is a critical determinant of clinical outcome after MI.

Current working models for heart failure include the cardiorenal model (excessive salt and water retention), the hemodynamic model (pump failure and excessive vasoconstriction), and the neurohormonal model (overexpression of biologically active molecules capable of exerting unfavorable effects on the heart and circulation). Each of these may be necessary but not entirely sufficient to explain all the causes of disease progression in the failing heart. After the myocardial insult and the initial decline in pumping capacity, a variety of compensatory mechanisms are evoked to restore cardiovascular function and normal homeostasis. Adrenergic, renin-angiotensin, and cytokine systems are activated systemically and locally in the myocardium in response to reduced cardiac output.^{18,19} A variety of circulating and tissue proteins and peptides (e.g., norepinephrine, angiotensin II, endothelin, aldosterone, tumor necrosis factor, interleukins) are generated in an initial adapting response. However, chronic overexpression of these biologically active molecules may fundamentally alter gene expression, changing protein synthesis in both myocytes and fibroblasts.

The biomechanical model for heart failure described by Mann and Bristow helps to explain the progression of heart failure independent of the neurohormonal status of the patient.²⁰ In fact, current medical therapy, acting against neurohormonal activation, tends to slow progression but fails to arrest the process of remodeling. In addition, many types of neurohormonal inhibition proved to be ineffective or even harmful in patients with heart failure.²¹

To explain the failure of neurohormonal antagonism, Mann and Bristow focus on LV size and geometric abnormalities as being responsible for progression of the disease. Geometric changes lead to structural abnormalities of the myocytes and of the myocardium, which worsen cardiac function and increase neurohormonal activation; this may make the cardiovascular system less responsive to normal homeostatic control mechanisms.²⁰

Left Ventricular Geometric Abnormalities in Ischemic and Nonischemic Ventricles

The determinants of LV geometry are shape, volume, and cardiac mass, and these three components may be altered by cardiac disease, which can be primarily degenerative, valvular, or ischemic in origin. Ischemic cardiomyopathy leads to a sequence of structural changes to compensate for the increased load produced from the nonfunctional akinetic or dyskinetic regions.²²

In anterior myocardial infarction, the LV apex is primarily involved, so regional changes affect the anterior, septal, and inferoseptal ventricular components. Globally, the elongation and widening of the ventricle occur proportionally to maintain a constant ratio (i.e., a constant *sphericity index*, or short ratio to long axis). However, when patients develop secondary mitral insufficiency, the

sphericity index is abnormal and the ventricle is more spherical. In the absence of mitral regurgitation (MR), therefore, the sphericity index fails to detect shape abnormalities in anterior postinfarction cardiomyopathy. The *conicity index* has been proposed to assess the conical shape of the apex and its changes after MI (Fig. 100-1).²³ Another important shape change that occurs after an anterior MI is the displacement of the papillary muscles laterally and toward the apex, which produces tethering of the posterior mitral leaflet and mitral restriction.

Alternatively, shape changes after an inferior MI are different²⁴: the short axis is widened more than the long axis is elongated, which leads to an increase in the sphericity index and accounts for the more frequent occurrence and the more severe degree of MR. Table 100-1 compares the geometric abnormalities that occur in anterior and inferior myocardial infarctions.²⁵

Nonischemic dilated cardiomyopathy exhibits a more spherical shape than ischemic cardiomyopathy: the short axis is enlarged, MR is more frequently involved, and wall motion is severely and diffusely hypokinetic. Pump function is markedly reduced and there are apparently no regional differences in contractility. However, biopsy studies show nonhomogeneous disease in many patients, with the amount of scarring and fibrosis ranging from 4% to 60% between the free wall and the septum, which may account for the failure of some types of surgery, such as the Batista operation, to reduce the ventricular cavity in patients with nonischemic dilated cardiomyopathy.^{26,27}

Rationale for Reshaping Cardiac Architecture

Figure 100-2 shows the spiral arrangement of myocardial fibers as reported in a very old anatomy atlas. Studies^{28,29} established that fiber orientation was a function of transmural location, with fiber direction being predominantly longitudinal in the endocardial region, transitioning into a circumferential direction in the midwall, and becoming longitudinal again over the epicardial surface. Such an alignment of fibers in double layers (left- and right-handed from the base to the apex) forms a double helix. These layers are not aligned parallel to one another;

rather, the myofiber sheets diverge within the LV wall, creating angulations with respect to the plane of the epicardial surface. These fiber angulations serve to resist deformation and to maintain the distribution of tension within normal limits at the three levels: longitudinal, radial, and circumferential. Moreover, this architecture gives to the heart a form resembling a geometric ellipsoid, which favors the direction of flow toward the aorta. When angulations are deformed by fiber disruption, fibrosis, or scarring of myocardial tissue, the shape of the ventricle loses its characteristics and its functionality (following the strict relationship between form and function). For a given fiber contractile status, the ejection fraction (EF) changes according to the shape of the ventricle, being low in a spherical ventricle (sphericity index, toward 1) and high in an elliptical shape (sphericity index, toward 0). In fact, macroscopic anatomic alterations can affect wall tension, which, according to the Laplace law, is directly proportional to LV pressure and chamber radius and inversely proportional to wall thickness. In animal models of myocardial damage or after MI in humans, ventricular remodeling alters the major determinants of wall stress,^{30,31} and functional impairment has been reported in the remote zones of dilated LV with geometric abnormalities.³² When the ischemic systolic dysfunction is superimposed on the use of preload to

TABLE 100-1 **Geometric Differences According to Site of Myocardial Infarction**

	Inferior	Anterior	P value

FIGURE 100-1 ■ Geometric measures in normal and dilated cardiomyopathy. Sphericity index (SI) is calculated as the short- to long-axis ratio (S/L), and conicity index (CI) as the apical to short-axis ratio (Ap/S). Apical diameter is determined by using the diameter of the sphere that best fits the apex. Note that the SI has the same value in normal subjects and in patients with dilated cardiomyopathy, because the elongation of the ventricle is proportional to the increase in width, so the ratio remains stable, whereas the CI is markedly abnormal in the patients.

FIGURE 100-2 ■ The three-dimensional architecture of the heart. From an eighteenth-century atlas of anatomy. (From Benninghoff-Goertler: *Atlas of anatomy*, vol II, Padova, Italy, 1996, Piccin Editore.)

improve cardiac output during exercise, the ventricle can be further dilated because of its inability to eject blood, starting a cycle that further deteriorates LV function. In addition, LV end-diastolic pressure can increase in the presence of reduced myocardial compliance (resulting from tissue stiffening), which tends to resist deformation, whereas increased stiffness leads to decreased systolic function.

A further increase in end-diastolic and end-systolic volumes (ESVs) leads to an adverse prognosis.³³ As part of the GUSTO (Global Utilization of Streptokinase and t-PA for Occluded Arteries) trial, Migrino and associates³³ evaluated ESV at 90 to 180 minutes into reperfusion during acute MI. They demonstrated that in successfully reperfused patients after MI, an increase in ESV beyond 40 mL/m² worsens prognosis in terms of both development of heart failure and mortality. A post-MI ESV index equal to or greater than 60 mL/m² carries a 1-year mortality rate of up to 30%. In the SAVE (Survival and Ventricular Enlargement) trial, left ventricular size was a strong independent risk factor for mortality after 2 years.³⁴

Even after coronary artery bypass surgery, patients with large ventricles have a worse prognosis. Yamaguchi and coworkers³⁵ identified LV ESV index greater than 100 mL/m² as an independent risk factor for the development of CHF in ischemic cardiomyopathy. These reports helped cardiac surgeons focus on the importance of reconstruction of the left ventricle in ischemic cardiomyopathy.

Left Ventricular Aneurysm or Ischemic Dilated Cardiomyopathy?

Left ventricular aneurysm was first described in the eighteenth century.³⁶ In 1816, Cruveilhier³⁷ attributed ventricular aneurysm to myocardial fibrosis, although its association with coronary thrombosis was not generally appreciated until a century later. It was not until Tennant and Wiggers showed paradoxical motion in acutely ischemic myocardium that the physiologic implications of ventricular injury became apparent.³⁸ Subsequently, Murray described systolic paradoxical expansion of acutely infarcted myocardium and correlated this with diminished cardiac output and falling blood pressure.³⁹ In 1967, Klein and coworkers⁴⁰ published a hemodynamic study on LV aneurysm that became a milestone in the field of mechanics and energetics of the left ventricle after an ischemic injury. Gorlin and coauthors were the first to state that when approximately 20% to 25% of left ventricular area is inactivated by any pathologic process, the degree that the myofiber must shorten to maintain stroke volume exceeds physiologic limits, and cardiac enlargement (Starling mechanism) must ensue to maintain adequate ejection of blood. With this concept, they anticipated the concept of LV remodeling and described the way MI relates to the genesis of aneurysm. Furthermore, they described that the aneurysm can be either dyskinetic (i.e., paradoxical expansion resulting during systole) or akinetic (i.e., myocardial fibrosis, calcification within the scar, thickened overlying pericardium, mural

thrombosis, and endocardial thickening may rigidify the aneurysm wall and prevent its expansion).

Gorlin offered the following definition:

An aneurysm is identified by a left ventricular angiogram as any akinetic or dyskinetic segment of myocardium. An akinetic segment is defined as a segment that appears to have no motion during systole, whereas a dyskinetic segment appears to bulge paradoxically during systole. Intraoperatively, an aneurysm is identified as a circumscribed area of scar, which is thin, often adherent to the pericardium and which may or may not bulge paradoxically during systole. The aneurysmal segment is easily outlined by looking for the area that puckers and collapses when the left ventricle is vented.

This cineangiographic and surgical definition of ventricular aneurysm is compatible with the pathologic definition: "A localized outpouching of the cavity of a cardiac chamber, with or without outward bulging of the external surface."⁴¹

Early revascularization, with either thrombolysis or primary percutaneous transluminal coronary angioplasty, has beneficial effects on infarct size and LV function and therefore has profoundly changed the picture of MI and its sequelae.⁴²⁻⁴⁴ However, even with early mechanical relief of the coronary occlusion, unfavorable global LV remodeling may occur. Bolognese and coauthors demonstrated that almost 30% of patients with excellent infarct-related artery patency at 6 months continue to undergo

LV remodeling.^{45,46} In patients with an anterior MI, this occurs more frequently when myocardial contrast echocardiography demonstrates a higher incidence of microvascular dysfunction. Figure 100-3 shows the progression of an anterior MI toward ischemic dilated cardiomyopathy in one of our patients. Figure 100-4 shows two of the shape abnormalities that may occur after successful early recanalization for anterior MI as analyzed by the centerline method.⁴⁷⁻⁴⁹ Thus, an acute MI, either anterior or inferior, may result in any of four types of shape abnormalities (Fig. 100-5).⁵⁰ This classification is incomplete because it does not take into account abnormalities occurring at the septum or at the lateral wall. However,

FIGURE 100-3 ■ Left ventricle (LV) angiography, 30-degree right anterior oblique projection. *Left*, Early after myocardial infarction, systolic frame. Note the small apical aneurysm. The left anterior descending artery was successfully reperfused. *Right*, The LV angiogram 1 year later showed marked end-systolic volume dilation of the ventricle, and the patient had symptoms of heart failure.

FIGURE 100-4 ■ Left ventricular (LV) curvature and regional wall motion analyses in two patients after an anterior myocardial infarction was successfully reperfused. LV shape on the left represents the true aneurysm, with the classic neck at the border between thickening and nonthickening myocardium. LV shape on the right represents the true dilated ischemic cardiomyopathy, without borders between thickening and nonthickening myocardium. Graphs below each silhouette represent the curvature analysis (*left*) and the centerline analysis (*right*). Curvature values, expressed as the reciprocal of the radius ($1/R$) on the ordinate, are measured from the aortic to the mitral plane around the ventricular perimeter. Shadowing indicates standard deviation of normal motion; the line indicates wall motion in the patient. The curvature of the apex is greater in the normal heart and reduced in the patient. Note the sharp variation of curvature values from negative (–) to positive (+) and from + to – in the patient on the left. Curvature values in the patient on the right are extremely reduced without variations (neither negative nor positive)—that is, the curvature is flattened all along the perimeter. Centerline analysis: regional wall motion of 45 chords around the LV perimeter is quantified. A%, Extent of asynergy; AB, anterobasal region; AL, anterolateral region; AP, apical region; B%, extent of curvature abnormalities; DI, diaphragmatic region; EDV, end-diastolic volume; EF, ejection fraction; FS, fractional shortening; IB, inferobasal. (From Baroni M, Barletta G: Digital curvature estimation for left ventricular shape analysis. *Image Vis Comp* 10:485–494, 1992; and Sheehan FH, Stewart DK, Dodge HT, et al: Variability in the measurement of regional left ventricular wall from contrast angiograms. *Circulation* 68:550–559, 1983.)

FIGURE 100-5 ■ Silhouettes of left ventricle (LV) shape abnormalities after myocardial infarction. Diagrams represent evaluation by angiography in 30-degree right anterior oblique projection. *Type 1*: LV shape is geometrically delimited by two systolic “borders” between thickening and nonthickening myocardium; the classic neck of the true aneurysm is evident. *Type 2*: The shape is characterized by only one border between thickening and nonthickening myocardium, not two borders as in type 1. *Type 3*: LV systolic shape is without borders (i.e., the curvature is flattened along the overall perimeter of the ventricle). *Type 4*: Double-site myocardial infarction (anterior and inferior). AB, Anterobasal region; AL, anterolateral region; AP, apical region; INF, inferior; PB, posterobasal region; RAO, right anterior oblique projection.

it is useful for assessing treatment results, especially after volume reduction surgery, when the results after repair of a true aneurysm look profoundly different from the results after surgery for types 2, 3, or 4. [Figure 100-6](#) shows an echocardiographic study from four patients with three types of shape abnormalities. Apical four-chamber and two-chamber views are shown.

Left Ventricular Aneurysmectomy

The first successful surgical correction of an LV aneurysm occurred in 1957.⁵¹ Denton Cooley described the technique of open resection and simple closure on cardiopulmonary bypass in 1958.⁵² This technique was the standard of the profession for the next 30 years. In 1968, Favaloro and colleagues⁵³ reported on a series of 130 patients who underwent resection for LV aneurysm, with a hospital mortality of 13%.

In 1979, Grondin and associates⁵⁴ reported on a series of 40 patients with aneurysms who were medically treated. They divided the group into those with and those without symptoms. After 10 years, survival was 90% in asymptomatic patients but only 46% in patients who were symptomatic at the time of diagnosis. The causes of death were predominantly CHF, thromboembolism, and arrhythmias. They suggested that mortality depended on aneurysm size, with large aneurysms conferring a higher risk. These reports implied that medical management resulted in improved survival, and they fostered a reluctance to use surgery to treat this disease. As recently

FIGURE 100-6 ■ Echocardiographic four-chamber (**A**) and two-chamber (**B**) views are shown in four patients after an anterior myocardial infarction. All patients have marked left ventricular dilation with low ejection fraction (EF), but the shapes are definitely different. Types 1, 2, and 3 are shown.

as 1983, Cohen and coworkers⁵⁵ recommended that aneurysms be resected only after maximal medical management (for heart failure, angina pectoris, recurrent thromboembolism refractory to anticoagulation, and refractory ventricular tachycardia) had failed.

In 1985, the concept of surgical repair of the LV aneurysm was altered. Newer techniques described by Jatene⁵⁶ involved excluding the dyskinetic scar when performing a circular endoventricular suture, and Dor and colleagues¹² began using an endoventricular patch to rebuild a failing ventricle after extended endocardectomy for ventricular tachycardia. The concept was to reduce the LV size and reconstruct a more elliptical cavity, treating the dilation in all its components (anterior, apical, and septal), as opposed to performing a linear resection^{57,58} of the aneurysm, which left untouched a septal dilation and created a distortion of the residual chamber. The concept of excluding all diseased tissue from the cavity was a fundamental improvement.¹² With this change in technique, a reduction was seen in hospital mortality as well as in late mortality. Dor and coworkers demonstrated that the technique is

FIGURE 100-7 ■ Left, Septal anterior ventricular exclusion (SAVE) procedure, with steps A to E. See text for explanation. Right, Survival rates after the SAVE procedure were slightly higher when the surgery was elective. The number of patients (*n*) surviving at each follow-up year is shown above the abscissa. (With permission from Suma H, Isomura T, Horii T, et al: Septal anterior ventricular exclusion procedure for idiopathic dilated cardiomyopathy. *Ann Thorac Surg* 82:1344–1348, 2006.)

applicable not only to dyskinetic but also to akinetic areas. As a consequence, the indications and patient selection for volume reduction surgery have changed.⁵⁹

DIAGNOSIS AND PATIENT SELECTION FOR SURGERY

Nonischemic Cardiomyopathy

LV reconstruction for dilated cardiomyopathy (the Batista procedure, or partial left ventriculectomy) has been abandoned, primarily because of unacceptable perioperative mortality and morbidity.²⁷ One reason for its failure was that the pathology of the whole chamber was assumed to be uniform and homogeneous. However, there is evidence that the disease is nonhomogeneous, and that the septal and lateral walls differ in scarring and fibrosis.^{60,61} Thus, in the Batista operation, if a minimally diseased lateral wall was excised and a very fibrotic septum was retained, postoperative LV function was adversely affected, even if the left ventricle was properly downsized.

Therefore, Suma and colleagues⁶¹ suggested an intraoperative echocardiographic evaluation to assess the regional contractile response to preload reduction, to aid site selection, and to improve surgical results. In the intraoperative echocardiography-guided volume reduction test, the initiation of partial cardiopulmonary bypass decompresses the dilated (stretched) chamber and induces functional changes of left ventricular wall motion and thickness. Identification of wall motion changes means that the most diseased region can be selected for exclusion, leaving the more viable muscle to resume function after restoration. This idea comes from experience in restoring the ischemic left ventricle, when the scar is evident and can be excluded. However, the concept of nonhomogeneity in nonischemic cardiomyopathy is new. Suma reports that if intraoperative echocardiography shows that the septum is the weakest part, the septal anterior ventricle is excluded. Septal anterior ventricular

exclusion (SAVE) was introduced by Suma and colleagues^{26,60,61} and called *pacopexy* by Buckberg and coauthors⁶² in recognition of the contributions of Francisco (Paco) Torrent-Guasp, whose ingenious anatomic concepts defined the helical ventricular myocardial band and furthered our understanding of the relationship between structure and function.^{14,63} To make an elliptical ventricle, a long and narrow endoventricular patch is placed along the septum with interrupted mattress sutures so that the septum and a part of the anterior wall are excluded (Fig. 100-7). In patients with nonischemic dilated cardiomyopathy and advanced New York Heart Association (NYHA) class, results in terms of survival rate are promising.

When intraoperative echocardiography shows that the weakest part is the lateral wall, Suma and coworkers⁶¹ perform a partial left ventriculoplasty (Fig. 100-8).

Asynergic Areas

Appropriate candidates for LV reconstruction have suffered an MI, have a dilated left ventricle, and have an asynergic area (either dyskinetic or akinetic) of 35% or more of the ventricular perimeter. These patients have symptoms of heart failure, angina, or intractable ventricular arrhythmias.

The left ventricle should be evaluated carefully with coronary angiography (ventricular angiography in right and left anterior oblique projections), by a complete echocardiographic study (four- and two-chamber views, and parasternal long- and short-axis views), or by a magnetic resonance imaging (MRI) study. The objectives of these imaging techniques are to assess parameters for patient selection (Box 100-2), treatment planning, and follow-up.

Patients with either akinetic or dyskinetic scar may benefit from SVR, and it is the *extent* of asynergy rather than the *type* of asynergy that is related to outcome after the surgery.⁶⁴ The region to be surgically excluded should be carefully evaluated for wall motion and thickening.

FIGURE 100-8 ■ Left ventriculoplasty, or Batista operation. **A**, Lateral partial ventriculectomy. **B**, Closure of the ventriculotomy.

BOX 100-2 Parameters for Patient Selection

- Internal dimensions of the ventricle
- Ventricular volumes (both in diastole and in systole)
- Ejection fraction
- Thickness and thickening of the wall
- Extent of asynergic area
- Status of the remote regions
- Presence or absence of viability
- Presence or absence of mitral regurgitation
- Mitral annulus size and left atrium size
- Right ventricular function

Wall motion assessment can be accomplished by LV angiography, echocardiography, or nuclear scintigraphy, but MRI provides a more accurate determination of LV volumes and EF, because it shows the epicardial and endocardial border from the base to the apex in a three-dimensional view.

LV angiography is a planar technique that shows at most two projections along the ventricle. It does not show the epicardial border, so it does not help in a calculation of thickening. However, application of the centerline method to LV angiography resulted in a reliable quantitative assessment of regional wall motion⁴⁹ with clear definition of asynergy. Echocardiography allows visualization of both the endocardial and the epicardial borders, so wall thickening and wall motion can be assessed. However, an echocardiographic method that precisely defines regional wall motion is not available. Therefore, wall motion is measured by the wall motion score index,⁶⁵ which results from a qualitative (thus subjective) evaluation of motion and is expressed by a number derived from the sum of the degree of asynergy at 16 different segments (normal, 1; hypokinetic, 2; akinetic, 3; dyskinetic, 4; aneurysmal, 5).

Echocardiography has several other limitations: (1) the LV apex is not adequately seen when the ventricle is enlarged (e.g., in dilated cardiomyopathy); (2) the endocardial border is often not clearly seen, which

FIGURE 100-9 ■ Cardiac magnetic resonance images with late gadolinium enhancement. *Left*, Normal subject, without myocardial scar. *Right*, An example of extensive transmural myocardial scar in a patient who will undergo surgical left ventricular restoration. The two-chamber view is shown. Note the bright myocardium extending from the basal anterior region to the apex and inferoapical region.

accounts for intraobserver and interobserver variability in measuring LV volumes and EF; and (3) many patients have comorbidities (e.g., obstructive pulmonary disease, obesity) that make the echocardiography images suboptimal.

Nuclear scintigraphic methods display endocardial border motion in planar views (with radionuclide angiography, labeling the blood pool) or the myocardium, including endocardial and epicardial visualization with gated single-photon-emission computed tomography. However, such studies require the use of radioactive tracers and are not available in all cardiac centers. Also, cardiovascular MRI is not available everywhere, and some patients have contraindications to the study (e.g., claustrophobia, presence of implantable cardioverter-defibrillator). However, it allows a most comprehensive evaluation with highly accurate and reproducible measurements in a single session.⁶⁶ The greatest usefulness of cardiovascular MRI is in the detection of myocardial scar with late gadolinium enhancement. Myocardial scar tends to accumulate a significantly higher concentration of gadolinium than normal myocardium. Ten to 20 minutes after infusion, scarred regions appear very bright, whereas normal myocardium appears dark, at typical imaging times. [Figure 100-9](#) shows a patient with extensive scarring in the anterior and apical territory. A predictor of myocardial viability is the ratio of the thickness of tissue exhibiting late contrast enhancement in a segment to the total LV wall thickness in that segment. Segments with nearly transmural extent of late contrast enhancement are highly unlikely to have recovery of function after revascularization.⁶⁷

Commercially available software dedicated to LV function analysis now provides a semi-automated assessment of regional wall motion, the extent of normal and abnormal contracting myocardium, and the percentage of scarred tissue ([Fig. 100-10](#)). This allows a prediction of myocardial viability without a need for pharmacologic stress. Cardiovascular MRI also allows quantification of regional deformation by radionuclide tagging and calculation of strain and strain rate, which can be particularly useful for examining the remote regions and the apical twisting and untwisting.⁶⁸ Torsion and twisting and

FIGURE 100-10 ■ Analysis of cardiac function using MARISA software (Magnetic Resonance Imaging System Analysis [Chase Medical, Richardson, Texas]). *Top left*, Wall motion analysis quantified as normal, hyperkinesia, hypokinesia, and akinesia. The percentage distribution of asynergy is calculated. *Top right*, Assessment of scar transmurality with late gadolinium enhancement. The extent of the transmurality from 0% to 100% is color coded, and the percentage of scarred tissue is calculated. *Bottom left*, Analysis of viability: the green area represents potentially viable myocardium that may improve with revascularization; the blue area represents the transmural, nonviable scar. *Bottom right*, Three-dimensional reconstruction of the left ventricle superimposed on the four-chamber view. The extent of the scar as evaluated by late gadolinium enhancement is shown.

untwisting movements of the apex (as opposed to the base) greatly contribute to blood ejection and to maintaining a good pump function; these mechanisms are reduced or even lost after an anterior MI, resulting in further impairment in cardiac function. Cardiovascular MRI tagging, however, is not routinely performed in clinical practice but is confined to research studies because the data analysis is laborious and time consuming and requires intensive computation. With the development of a tissue Doppler imaging technique and the two-dimensional “speckles” or endocardial border tracking analysis,^{69,70} it is easier to measure systolic and diastolic deformation either longitudinally or radially. Vector direction gives the clockwise and counterclockwise directions of contraction, which is particularly useful for assessing torsional mechanics at the apical level. An analysis of untwisting also provides information on diastolic function, at least on rapid filling.

Status of Remote Regions

The quantification of remote regions is performed to determine whether a patient is a candidate for an SVR procedure, and these regions are often not evaluated by

conventional imaging studies. After an anterior MI, remote regions may show hypokinesia or even akinesia resulting from critical coronary disease in the right or left circumflex coronary artery (hibernating myocardium), or remote myocardium may be dysfunctional in the absence of coronary stenosis because of the high local tension that reduces shortening. Several years ago, we demonstrated³² that SVR induced an improvement in remote nonischemic regions in patients with anterior infarction; in that study, we excluded patients with significant stenosis in the right and left coronary arteries. Nowadays, with cardiovascular MRI, we can predict the recovery of function in ischemic, hibernating areas that will benefit from concomitant coronary artery bypass grafting (CABG), and we can also predict whether dysfunctional, nonischemic segments may recover after volume reduction. Therefore, we propose a term other than *hibernating* or *stunned* for dysfunctional nonischemic myocardium in dilated cardiomyopathy—*exhausted myocardium*—which implies recovery of function if the hemodynamic burden that imposes a high wall tension is relieved by SVR.

On the other hand, the detection of scar in remote regions by late gadolinium enhancement may predict an unsatisfactory pump improvement and a higher mortality

rate after SVR. A significant scarring in a myocardial segment precludes, in fact, the likelihood of postoperative contractile recovery of that segment.

In summary, extensive preoperative imaging studies are necessary for selecting patients, planning treatment, and evaluating the results of SVR. Cardiovascular MRI is the best option, because it provides the surgeon with all the necessary information for planning an effective, comprehensive surgery tailored to the individual patient, and all the information can be obtained in a single examination taking less than 1 hour.

Finally, cardiologists, radiologists, and surgeons must collaborate to improve knowledge about patient selection and to achieve an optimal surgical outcome.

SURGICAL VENTRICULAR RESTORATION FOR ISCHEMIC CARDIOMYOPATHY

Left ventricular reconstruction by endoventricular circular patch plasty repair was described and proposed by Dor and colleagues in 1984¹² for rebuilding the left ventricle after an MI, either during the acute phase (surgical treatment of septal rupture or refractory ventricular arrhythmias according to the Harken technique⁷¹) or in patients with chronic MI and with LV asynergy (akinesia or dyskinesia) to exclude all the akinetic nonresectable areas (e.g., septum and posterior wall). In addition, a complete coronary revascularization is achieved and mitral repair or replacement is performed if needed.⁷²

The term *surgical ventricular restoration* includes operative methods that reduce LV volume and restore ventricular elliptical shape. The concept of reducing wall stress through the surgical restoration of LV cavity size and geometry is the guiding principle behind this innovative technique.

Since the first description by Dor and colleagues,¹² the procedure has been adopted by many surgeons, but it is not widely used because surgeons have been unwilling to incise and exclude the akinetic normal-appearing segments often encountered after early reperfusion. Instead, CABG is performed, and the nonfunctioning akinetic muscle containing deeper scar is left undisturbed.⁷³

The technique has not been standardized, and surgeons use essentially four variations of LV reconstruction to exclude the septum. These include a linear closure by

Jatene,⁵⁶ a modified linear closure by Mickleborough,⁷⁴ a circular closure with a patch by Dor and Menicanti,⁷⁵ and a double cerclage closure without a patch by McCarthy.⁷⁶ All of these techniques involve an incision into the diseased anterior wall, an exclusion of the entire diseased segment, and a reduction in ventricular cavity size. In the majority of patients, reconstruction is done on the anterior portion of the left ventricle. However, reconstruction has also been performed on the posterior wall after circumflex or right coronary artery occlusion. Most of these patients undergo concomitant coronary artery bypass, and many also undergo mitral valve repair.

Surgical Details of Anterior Surgical Ventricular Restoration

Surgical LV restoration as performed since 2001 by our group at the San Donato Hospital in Italy is conducted on the arrested heart with antegrade crystalloid or cold-blood cardioplegia. CABG is first performed, as completely as possible, almost always on the left anterior descending coronary artery, to preserve the upper part of the septum and to guarantee complete revascularization. The ventricle is opened at the middle of the scar on the anterior wall, with an incision parallel to the left anterior descending artery, starting from the midportion and proceeding toward the apex. The internal part of the cavity is examined, and thrombi are removed if present. The mitral valve is repaired, when necessary, through the ventricular opening with a double-armed stitch at the posterior annulus, from trigone to trigone, and the mitral orifice is undersized with a 26-mm valve sizer.⁷⁷

In July 2001, we introduced the Mannequin (Chase Medical, Richardson, TX), which we fill with 50 to 60 mL of saline per square meter of the patient's body surface area to optimize the size and shape of the new ventricle. This TRISVR technique is a refinement of the Dor technique that introduced a sizer device in 1998, which allows standardization of the procedure. The device is inserted into the LV cavity after an incision is created (Fig. 100-11) and then carefully inflated with saline when it is seated properly in the cavity, to avoid the risk of inflating the device when it is in the mitral valve. The new apex will be placed at the apex of the Mannequin, and this is the starting point for the 2/0 endoventricular circular suture. The suture is carried

FIGURE 100-11 ■ The use of the intraventricular mannequin during surgical left ventricle reconstruction. SVR, Surgical ventricular restoration.

FIGURE 100-12 ■ Sequence of a suboptimal endoventricular suture. **A**, Suturing is done on a plane parallel to the mitral valve. **B**, The suture is tightened. **C**, The patch is inserted, and its resultant position is parallel to the mitral valve.

FIGURE 100-13 ■ Angiography preoperatively (Pre-op) and postoperatively after surgical left ventricular reconstruction (Post-SVR). *Left*, Before surgery. *Right*, After surgery. Note the spherical left ventricular chamber achieved after surgery.

deep toward the septum and up toward the aortic outflow tract on an oblique plane to reconstruct an elliptical shape, not a spherical chamber. The suture is then brought toward the lateral wall, and back to the apex, and tightened on the Mannequin. The plane of the closure should not be parallel to the mitral valve (Fig. 100-12). If the closure plane is parallel to the mitral valve, the result is a spherical chamber (Fig. 100-13). The shape of the device is appositely conical with a physiologic short-to-long-axis ratio to reconstruct a more physiologic, elliptical shape. After positioning the new apex, the surgeon places the circular stitches at the transitional zone (between the scarred and the sound tissue). When the ventricle is not very enlarged, the Mannequin reduces the risk of creating a residual cavity that is too small. It is also useful when the infarcted region is not clearly demarcated, as occurs in dilated cardiomyopathy (type III silhouette [see Fig. 100-5], as described by our group).⁵⁰ In this circumstance, the transitional zone between

BOX 100-3 Surgical Pitfalls

- Incorrect indications
- Incomplete revascularization
- Embolism
- Cavity dimension: too large or too small
- Cavity shape: spherical or distorted

scarred and nonscarred myocardium is not well defined, and the Mannequin allows rebuilding of the ventricle in an elliptical way with a proper residual size. Box 100-3 shows surgical pitfalls during SVR.

The use of the Mannequin is a refinement of the technique introduced by Dor in 1998 using a toy balloon. The size of the device is chosen by multiplying the body surface area of the patient by 50 or 60 mL. This choice is empirical: we prefer to leave a residual chamber with a normal volume (52 ± 13 mL/m² in a series of 52 normal subjects from our echocardiography laboratory).²³

The technique used by Menicanti is shown in Figure 100-14. In some circumstances, the inferoapical region is dilated after an anterior MI because of left dominance of the anterior descending artery. When the device is in place during reconstruction, a gap between the transitional zone and the position of the new apex is evident; in such cases, we thread a direct suture from inside to reduce the inferior dilation and to lift up the new apex, bringing the lateral wall toward the septum (Fig. 100-15). Usually, this suture runs for 1 to 1.5 cm. In chronic anterior MI, the LV apex, in addition to being enlarged, is also shifted inferiorly and posteriorly (Fig. 100-16), and this alters the direction of flow toward the aorta. Thus,

FIGURE 100-14 ■ **A**, Schematic representation of surgical left ventricular reconstruction as performed by Menicanti. The device is inserted in the correct position, and the patch is sutured when the device is in place and parallel to the septum (i.e., oblique to the aorta). In photographs from the operating room (**B-D**), mammary anastomosis to the left anterior descending artery is completed, as is the venous sequential graft. **B**, The Dacron patch is prepared with an elliptical shape and appropriate size. **C**, The patch is trimmed during the suturing. **D**, Suturing of the completed patch.

FIGURE 100-15 ■ To reduce the inferior wall dilation, a direct suture is brought from inside. In this way, the lateral wall is approximated to the septum, and the new apex is lifted up to a more anterior position.

FIGURE 100-16 ■ The shape of the left ventricle, obtained by Fourier analysis of curvature as seen by 30-degree right anterior oblique angiography. Reconstructed silhouettes are averages for normal subjects and for patients with anterior myocardial infarction (MI). The apex in the patient silhouette is enlarged (less conical) and shifted downward and toward the mitral plane in both systole (inner line) and diastole (outer line). Numbers refer to the 90 chords as identified by the centerline.⁴⁹ (From Baroni M, Barletta G: Digital curvature estimation for left ventricular shape analysis. *Image Vis Comp* 10:485-494, 1992.)

it is very important for the surgeon to give the apex a conical form in an anterior position, because this reestablishes the correct blood vortex at the apex and a more physiologic direction of flow.

The Mannequin is then removed and the opening of the ventricle is closed with a direct suture if it is less than 3 cm, or it is closed with an elliptical synthetic patch if it is greater than 3 cm. The suture attaching the patch is continuous and conducted in an everting manner, starting from the deeper septal part of the opening, going toward the apex, and then up again toward the lateral wall.

Mitral Valve Repair during Surgical Ventricular Restoration

We have adopted a new surgical technique to repair the mitral valve during SVR with CABG. Because our technique reduces the dimensions of the mitral annulus, we avoid an atrial approach to the annulus and access it through the same ventricular incision that is used to perform SVR (Figs. 100-17 and 100-18). After the LV cavity is opened, each papillary muscle head is identified, and the mitral valve leaflets and chords are evaluated. The posteromedial fibrous trigone is visualized, and a pledgeted 2/0 polyester suture is placed from the ventricular side to the atrial side. The two arms of this suture progress with a running stitch toward the anteromedial trigone, carrying it to a few millimeters from the mitral annulus with biting sutures into atrial and ventricular muscle. The suture arms pass through the anterolateral trigone, and a second pledget is inserted. The entire posterior annulus becomes completely bounded by this suture. To undersize the mitral annulus and avoid valve constriction, a 26-mm sizer is introduced into the mitral orifice, and the suture is tied against the second pledget.

We analyzed the shapes of the left ventricle in a series of patients with MR undergoing SVR and compared them with a series of patients without MR. Quantitative shape analysis showed a flattening of the inferior curvature in patients with MR (Fig. 100-19), as well as reduced regional fractional shortening by centerline analysis. Patients with MR also had a less concave systolic inferior

Mitral valve repair by endoventricular approach

FIGURE 100-17 ■ Intraoperative mitral valve repair via the ventricular approach. Note the orientation of the patch at the end of the procedure: it is placed very deep into the septum and oblique to the aorta.

segment. Furthermore, overall shape differed significantly, with more spherical chambers in patients with MR than in those without (Table 100-2). Between July 2001 and April 2008 at the San Donato Hospital, 116 of 458 patients undergoing SVR with CABG had an associated mitral repair. Operative cardiac mortality was 12.9% (15/116), significantly higher than the 4.7% mortality without mitral repair (16/342). Figure 100-20 shows geometric features of the mitral valve before and after surgery. We focused on anterior infarctions to avoid the changes in the submitral apparatus that occur with inferior infarction, and because LV shape changes that occur in anterior infarctions are the primary determinants of functional MR in patients with severe heart failure. Increased sphericity plays a central role in the development of functional MR, because it progressively widens the LV transverse diameter; our findings (see Table 100-2) confirm this causation.

The decision for valve repair is based on preoperative measurements of ventricular volume, annular size, and the degree of MR. Formerly, we repaired moderate or severe MR (grade 3 or 4+) and mild MR (grade 2+) if the annulus was dilated (>38 mm). In a recent series of patients with mild MR treated with SVR but without mitral repair,⁷⁸ the outcome was excellent in terms of improvement in function and survival. Thus, successful surgical treatment of functional MR depends on reestablishing normal leaflet coaptation by changing the architecture of the mitral annulus or of the ventricular wall, or both. Consequently, surgical interventions include coronary revascularization, reducing mitral annulus, and restoring LV shape to reduce tethering and

ventricular volume. The mitral annulus can be reduced with a prosthetic ring via the atrial approach or by annular suture of the posterior ring via a ventricular approach.⁷⁷ Downsizing the ring is essential to optimize the extent of coaptation, as emphasized by Bolling and colleagues.⁷⁹

Surgical Details of Posterior Surgical Ventricular Restoration

Limited data are available on surgical repair for LV dilation resulting from inferior MI.⁸⁰ Changes in LV

geometry vary with the site of coronary occlusion—for example, the classic posterior aneurysm with a bulging of inferior wall and good contraction in the remaining cavity, or global dilation of the LV chamber with regional wall dysfunction at the inferior and posterobasal region. Although both conditions can lead to secondary MR, it happens more frequently in the global dilation because of the enlargement of the transverse diameter and the globular shape. Surgery for the posterior aneurysm generally involves a patch to close the neck of dilation, but the treatment of global dilation of the inferoposterior wall is more complex, especially because of the relationship between the scar and the dilation with respect to the papillary muscles.

A very short incision is made in the scar, or where a depression is evident during venting. Through this incision, the position of papillary muscles is carefully checked. After an inferior MI, there are two possibilities: (1) the dilation is mainly between the two papillary muscles or (2) the dilation is between the posteromedial papillary muscle and the septum, which is deeply involved (Fig. 100-21). We use two techniques for LV dilation after an inferior MI. The first, shown on the left in Figure 100-22, begins with opening the scarred wall at the level of the scar or at the level of the collapsed area, parallel to the posterior descending artery. A continuous 2/0 Prolene suture reapproximates the two papillary muscles

FIGURE 100-21 ■ Two types of lesions occur after inferior myocardial infarction, as recognized by the position of the papillary muscles after the incision at the posterior scar. *Right*, The dilation is between the two papillary muscles. *Left*, The dilation is between the posteromedial papillary muscle and the septum.

and excludes the entire dilated zone. The suture is started at the beginning of the dilation (sometimes just at the mitral annulus) and continues toward the apex. In the second procedure (see Fig. 100-22, on the right), the wall is opened, and then the continuous suture is brought past the posteromedial papillary muscle, bringing the posterior wall against the septum. In this way, when MR is determined only by the displacement of the posteromedial papillary muscle, mitral insufficiency is repaired. Our results from about 125 patients who received posterior SVR show a significant decrease in end-diastolic and ESV and an improvement in EF and clinical status. Operative mortality rate is higher than in anterior SVR (7.2%) and survival rate is significantly lower.⁷⁷

OUTCOMES

Many groups have found the results of SVR to be favorable and consistent.^{15,59,81-104} In Table 100-3, a summary of the best-evidence studies, we have recorded the number of patients enrolled, the number of associated mitral procedures, the operative (30-day) mortality, and improvements in ESV and EF. Follow-up is also reported, when available.

The largest reported series (from the RESTORE group, a team of cardiologists and surgeons from 12 centers on four continents¹⁰²) and, more recently, a

single-center experience from Menicanti and associates⁹⁸ reported on SVR for 1198 and 1161 patients with anterior MI, respectively, and demonstrated that SVR improves symptoms and long-term survival in patients with ischemic cardiomyopathy and severe heart failure. The beneficial effects of SVR in improving cardiac function and in reducing LV volume, ventricular arrhythmias, and MR has been largely accepted.^{59,72,85-89,92,95,97} A reduction in mechanical intraventricular dyssynchrony has also been demonstrated.¹⁰⁵⁻¹⁰⁷

The RESTORE group (Reconstructive Endoventricular Surgery returning Torsion, Original Radius and Elliptical shape to the left ventricle), organized by Gerald Buckberg in 1998, is the first international team to find evidence that for patients with CHF, rebuilding the heart by addressing a geometric solution (to bring back to normal the shape and size of the damaged ventricle) is an effective method to treat ischemic dilated cardiomyopathy.¹⁰⁸

Data reported in the literature are in close agreement: SVR results in a significant acute improvement of systolic function, significant acute reduction of mechanical dyssynchrony, and significant reduction in wall stress. Although data are more limited for changes in diastolic function, these changes are comparable with the changes in patients with preserved LV function who undergo elective CABG.^{109,110} The acute beneficial effects on systolic function are largely maintained in the long term, and

FIGURE 100-22 ■ Two techniques of posterior repair of the left ventricle of a patient with an aneurysm. The image shows the posterior wall of the ventricle. The diagrams show the two techniques, from top to bottom on the left, and from top to bottom on the right. *Left*, After the opening of the scarred wall, the base of the papillary muscles is identified, and the dilation is observed to be mainly between the two papillary muscles. A 2/0 Prolene suture is started at the beginning of the dilation (sometimes at the mitral annulus) and continues toward the apex, excluding all the damaged tissue from the cavity. *Right*, After the wall is opened, a continuous suture is threaded past the posteromedial papillary muscle, bringing the posterior wall against the septum. In this way, when mitral regurgitation results from the displacement of the posteromedial papillary muscle, mitral insufficiency is repaired. LV, Left ventricle; RV, right ventricle.

SVR induces a significant reverse-remodeling associated with clinical improvement and improved survival. Interestingly, the entity of EF improvement and of LV volume reduction is uniform in all the reported series, varying from +6 to +15 (absolute points) for EF, and from 30% to 45% reduction for LV ESV (see Table 100-3). Also, survival rates appear uniform among different studies, being an average of nearly 80% at 5 years and 60% at 10 years. Survival rates in patients with advanced NYHA functional class are particularly gratifying, being 88% at 3 years in NYHA class 3 and 68% in NYHA class 4, as reported by Williams and associates,⁸⁴ and 50% at 5 and 10 years, as reported by Menicanti and colleagues (Fig. 100-23).⁹⁸ Moreover, the rate of rehospitalization for heart failure is reported to be low.^{98,102} These results are similar to those reported at 6 months after heart transplantation, and a study from Cotrufo and coworkers showed no differences in mortality, clinical improvement, and survival rate between a comparable group of patients with dilated ischemic cardiomyopathy who underwent either SVR or heart transplantation.¹¹¹

Surgical Ventricular Restoration and Diastolic Function

Data on diastolic function after SVR are limited. Experimental studies and theoretical considerations suggest that SVR induces diastolic dysfunction.¹¹² The effect of SVR on diastolic function was recently the focus of two studies by Tulner and colleagues.^{104,106} The effects of SVR on ventricular function and the related effects of diastolic dysfunction on outcome after SVR have not been well studied until recently. However, a study by Tulner and colleagues¹⁰⁶ (and see the accompanying editorial by Burkoff and Wechsler¹¹²) was the first in which the diastolic pressure-volume relationship was measured in patients before and after SVR. They showed that diastolic compliance appears to be reduced early after SVR, leading to a reduction in stroke volume. These effects may result from postoperative edema, because pulmonary pressures late after SVR are significantly reduced.

The factor most likely to affect diastolic function is the size of the residual LV cavity. Excessive volume

reduction probably causes diastolic compliance to shift farther to the left on the pressure–volume curve than end-systolic elastance, thereby producing diastolic heart failure. This may have been the genesis of the unsatisfactory results obtained with standard linear aneurysm repair.¹¹³ With the introduction of sizing devices for LV reconstruction, the risk of leaving a too-small residual cavity is almost absent, but there is currently no objective evidence to support the selection of a particular postoperative size.

In an earlier paper,¹⁰⁵ we reported changes in diastolic function after SVR in a series of 30 patients evaluated by pressure–volume loops. We found significant improvement early after surgery in filling pressure and in parameters of diastolic function (peak filling rate, time to peak filling rate, and tau) (Fig. 100-24), as well as in diastolic pressure–volume curves (Fig. 100-25).

In a recent paper, we reported that end-stage or restrictive diastolic dysfunction (i.e., the ratio of early to late diastolic filling is >2) was associated with early mortality in 254 patients undergoing SVR.⁹⁸ Our group also made an interesting observation in regard to the relationship between diastolic worsening (defined as an increase of at least one class level of diastolic filling pattern) and the preoperative LV shape: patients with nonaneurysmal lesions and a higher sphericity index tended to have a higher rate of worsening of diastolic function.¹¹⁴ Furthermore, we have analyzed time-course changes in diastolic function after SVR and found that at follow-up (average time from surgery, 8 months), the majority of patients did not have significant changes in diastolic function, but 20% developed a restrictive pattern. Figure 100-26 compares the preoperative characteristics of patients who developed diastolic restriction and the characteristics of

those who did not. Larger LV diameters, greater left atrium size, increased sphericity index of the LV chamber, and lower EF were significantly associated with the development of diastolic dysfunction.²⁵

Surgical Ventricular Restoration and Left Ventricular Dyssynchrony

Left ventricular dyssynchrony has been recognized as a condition leading to LV dysfunction, both in ischemic and nonischemic dilated cardiomyopathy. Cardiac resynchronization therapy (CRT) is a treatment option in symptomatic patients with end-stage heart failure and LV mechanical dyssynchrony. Current indications for CRT in patients with drug refractory end-stage heart failure are NYHA class III–IV symptoms, LV EF less than 35%, QRS duration greater than 120 msec, and a left bundle branch block configuration. Large randomized, placebo-controlled studies have demonstrated the beneficial effects of CRT on symptoms, exercise capacity, and quality of life.^{115,116} Despite these beneficial effects, however, a consistent number of patients (almost 50%) do not benefit from CRT. The reasons are related to difficulties in defining asynchrony and to the presence of scarred regions that cannot respond to therapy.¹¹⁷ In patients with end-stage heart failure, LV mechanical dyssynchrony, whether interventricular or intraventricular, is related to electrical, structural, and morphologic features.^{118,119}

We tested the capacity of geometric rebuilding by SVR to restore a more synchronous contractile pattern without the use of an exogenous pacing input.¹⁰⁵ Thirty patients (58 ± 8 years old) undergoing SVR at the

FIGURE 100-24 ■ Predischage changes in diastolic parameters induced by surgical ventricular restoration. The improvement was significant for all parameters. EDV, End-diastolic volume

FIGURE 100-25 ■ End-diastolic pressure–volume curves obtained preoperatively (1), early postoperatively (2), and after 1 year (3) in a series of patients undergoing surgical ventricular restoration. Values are means. Note the marked left shift of the curve on the abscissa and the reduction of end-diastolic pressure. At 1 year, the curve shifts to the right, but it remains significantly improved with respect to the baseline (personal unpublished observations).

Cardiothoracic Centre of Monaco were prospectively evaluated with a protocol that used simultaneous measurements of ventricular volume and pressure to construct pressure–volume (P/V) and pressure–length (P/L) loops. Mean QRS duration was normal (100 ± 17 msec). Preoperative LV contraction was highly asynchronous. Endocardial time motion was either early or delayed at the end-systolic phase, yielding P/L loops with abnormalities in morphology and orientation. Postoperatively, SVR resulted in a leftward shifting of P/V loops and an increased area; endocardial time motion and P/L loops almost normalized (Fig. 100-27). The hemodynamic consequences of SVR included improved EF, reduced end-diastolic and ESVs, more rapid peak filling rate, and improved mechanical efficiency resulting in

mechanical intraventricular resynchronization that improved LV performance. This SVR-induced resynchronization has been confirmed in other studies.^{107,109}

The observed intraventricular dyssynchrony stems from asynchrony of the component parts of the LV chamber (structural nonhomogeneity). SVR accomplishes exclusion of scarred and thinned myocardium contiguous to normal, nearly normal, or ischemic tissue (Fig. 100-28).

Surgical Ventricular Restoration and Ventricular Arrhythmias

Another field in which SVR has demonstrated efficacy is that of ventricular arrhythmias (VAs). Complex, malignant VA frequently occurs in patients with ischemic dilated cardiomyopathy and may be responsible for sudden death in this population. Myocardial tissue heterogeneity increases susceptibility to ventricular arrhythmia, and this heterogeneity can be indexed by cardiac MRI.¹²⁰ The presence of infarcted tissue or scar forms the substrate for malignant reentrant arrhythmias,¹²¹ and MRI can, in principle, detect such a substrate because of its ability to delineate necrotic myocardium at all stages of infarct healing.¹²²

Infarcts can have marked spatial heterogeneity, with areas of necrosis interspersed with bundles of viable myocytes, particularly in the border zones and periphery of the infarct.¹²³ Tissue heterogeneity in these regions may create areas of slow conduction that generate the substrate for the development of lethal reentrant arrhythmias.¹²⁴ Increased mechanical loading of the heart, as occurs in dilated cardiomyopathy, is often associated with arrhythmias, the so-called stretch-induced arrhythmias. The alteration of the cardiac mechanical properties developing early in heart failure is accompanied by action

FIGURE 100-26 ■ Preoperative characteristics of patients who developed diastolic restriction after surgical ventricular restoration. Left ventricle (LV) diameters, left atrium size, sphericity index of the LV chamber, and ejection fraction (EF) were significantly worse in those who did not develop restriction. *Diast*, Diastolic; *Syst*, systolic. (Data presented by the authors at a meeting of the European Association for Cardiothoracic Surgery, Barcelona, Spain, September 2008.)

potential lengthening, which is modulated by an acute stretch. The stretch induces a mechano-electric feedback that is the common pathway responsible for the induction of VAs.¹²⁵

Di Donato, Dor, and associates¹²⁶ described a large series of patients with spontaneous or inducible ventricular tachycardia and compared them with patients who did not have arrhythmias. The study group included 87 patients with clinical documented ventricular arrhythmias and inducible or noninducible ventricular tachycardia (“spontaneous”), 105 patients with no clinical arrhythmia but with inducible arrhythmia in an electrophysiologic study (“inducible”), and 190 patients without clinical or inducible ventricular tachycardia (“no arrhythmia”).

A preoperative ESV index helped define the potential for preoperative arrhythmias. For the “spontaneous” patients, it was greater than 120 mL/m²; for the “inducible” patients, it was greater than 100 mL/m²; and for the “no arrhythmia” patients, it was less than 100 mL/m². SVR induced a significant reduction in inducible ventricular tachycardia—from 41% preoperatively to 7% at early study, and it was still 7% 1 year later (Fig. 100-29). Cardiac mortality was low at 5 years and not significantly

different between the spontaneous and the nonspontaneous groups (Fig. 100-30).

For this series of patients, Dor added extended non-guided endocardectomy and cryoablation at the transitional zone in patients with spontaneous and inducible arrhythmias, and to address a chamber size and shape factor during the SVR, he included in the procedure the following: resection of scar (a trigger of arrhythmias), septal exclusion, and cavity reduction by endoventricular patch (to reduce stretch), while supplementing the procedure with coronary grafting (to relieve ischemia) and mitral repair (to reduce wall tension), when needed. Dor’s success in antiarrhythmic management is supported by others who also perform cryosurgery,^{86,94} but no single factor can be identified to account for the high electrical success rate in these patients and for the low incidence of sudden death. A reasonable interpretation of these findings is that SVR addresses all the components that may activate ventricular arrhythmias (electrical and mechanistic volume-related cause), and that ventricular rebuilding deals effectively with the functional reentry circuit that can produce ventricular arrhythmias and simultaneously slows progression of heart failure in patients with dilated heart CHF.

FIGURE 100-27 ■ Pressure-length (P/L) loops constructed at the 45 chords of the ventricular perimeter (identified by the center-line method) are reported at different regions before and after surgery in a single patient. Note the abnormalities in size, shape, and orientation of the P/L loops before surgery (Pre-op) and the improvement after surgery (Post-op). P/L loops after surgery almost normalized, with squared shapes caused by rectilinear isometric phases.

Coronary Artery Bypass Surgery

Coronary bypass surgery is an important treatment for ischemic cardiomyopathy, but there is no evidence that the bypass procedure is superior to optimal medical therapy in patients with ischemic heart failure. Before the STICH trial, evidence of the benefit of surgical revascularization in patients with LV dysfunction and coronary artery disease was reported in old studies. The Veterans Affairs Cooperative Study of Coronary Bypass Surgery demonstrated a survival advantage for patients with impaired ventricular function who underwent revascularization compared with those who were medically treated.^{127,128} In the Coronary Artery Surgery Study, patients with mild or moderately impaired ventricular function had an improved survival after CABG compared with those who were medically treated.¹²⁹ Unfortunately, few patients with severe LV impairment were included. A second Veterans Affairs trial in patients with unstable angina also demonstrated a survival advantage in patients with abnormal LV function who underwent bypass surgery.¹³⁰ The results of these studies have been further supported by data from the SOLVD (Studies of Left Ventricular Dysfunction) studies and other reports.¹³¹

Despite this information, surgeons were reluctant to operate on patients with poor ventricular function, because it usually translated into poor surgical outcome. Fortunately, this has changed, because the outcome after CABG in the setting of severe LV dysfunction has improved significantly. Perioperative mortality in more recent series has decreased and now approaches 2% to 8% in many institutions. Late survival, angina status, and NYHA class have improved in follow-up periods. However, LV dysfunction remains a major marker of increased morbidity and mortality after CABG. Patients with an EF of less than 20% are four times more likely to develop low cardiac output syndrome compared with patients with normal EF. In the CABG Patch trial, patients with preoperative CHF had twice the perioperative mortality than did patients with normal ventricular function.¹³²

FIGURE 100-28 ■ Endocardial time-motion at 45 chords (identified by the centerline method) at three regions is shown before and after surgical ventricular restoration in one patient. After surgery, almost all segments reach the end-systolic phase synchronously, whereas almost none did so preoperatively despite a normal duration of QRS. This behavior reflects intraventricular dyssynchrony. ES, End-systolic phase.

FIGURE 100-29 Inducible ventricular tachycardia (VT) at electrophysiologic study before and after surgical ventricular restoration in a large population treated at the Cardiothoracic Centre of Monaco. The electrophysiologic protocol was not aggressive (up to two extra stimuli at two different cycle lengths) and was the same at the three tests. VT is no longer inducible in a significantly high proportion of patients, both at discharge and after 1 year (only 7% are still inducible postoperatively). CI, Confidence interval; PVS, programmed ventricular stimulation.

FIGURE 100-30 Kaplan-Meier survival curves in patients with spontaneous ventricular tachycardia (VT) and without ventricular arrhythmias who underwent surgical ventricular restoration. No significant difference was observed.

Coronary Artery Bypass Surgery with or without Surgical Ventricular Restoration: Insights into the STICH Trial

The STICH trial was designed to verify two hypotheses on a large population of patients affected by ischemic CHF and LV systolic dysfunction who were randomly assigned to receive medical therapy alone or combined with CABG (Hypothesis 1) and CABG alone or CABG plus SVR (Hypothesis 2).¹³³

The results of Hypothesis 2 showed that SVR combined with CABG had no impact over CABG alone on

mortality, heart failure hospitalizations, exercise tolerance, or quality of life.¹³⁴

Several major limitations of the STICH trial have already been noted,¹³⁵ including: (1) patient inclusion bias (i.e., many patients whose primary surgeons considered SVR to be clinically indicated were not randomized, characterized, or studied); and (2) the average reduction of ESV in the SVR group was much smaller than planned (raising serious questions about whether the procedure was performed properly in a majority of cases). Based on that, our group analyzed the impact on survival of a residual left ventricular end-systolic volume index (LVESVI) of greater than or less than 60 mL/m². We showed that LVESVI after SVR affects the probability of death, being significantly higher in patients who remain with a postoperative LVESVI of greater than 60 mL/m².¹³⁶ We hypothesized that the lack of additional improvement in terms of survival in the SVR group observed in the STICH trial might be a result of the inadequate volume reduction, which left the patients in the two arms at identical risk. Witkowski and colleagues confirmed this observation showing that a residual post-surgical LVESVI of at least 60 mL/m² was independently associated with a fivefold increase of death and rehospitalization for heart failure at 2 years' follow-up after SVR.¹³⁷ Furthermore, a more recent analysis of the STICH trial data showed that SVR combined with CABG conferred a survival benefit compared with bypass alone with the achievement of a postoperative end-systolic volume index of 70 mL/m or less.¹³⁸ In the meantime, the Task Force on Myocardial Revascularization of the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS) recognized the merit of SVR, which has been included as a surgical option combined with CABG in selected heart failure patients with a scar in the LAD territory and a baseline LVESVI greater than or equal to 60 mL/m² (Class of Recommendation IIb; level of evidence B).¹³⁹

The results of Hypothesis 1 (1212 patients with an ejection fraction of 35% or less and coronary artery disease amenable to CABG randomly assigned to medical therapy alone or medical therapy plus CABG) were not far different.¹⁴⁰ No difference was observed in the primary end point of death for any cause; however, cardiovascular deaths were reduced compared with medical therapy alone.

It has been observed that the trial, in spite of the acronym, was a study of ischemic heart disease rather than heart failure per se. However, although it is true that only 37% of patients had severe heart failure symptoms (NYHA functional class III and IV), it should be outlined that only 4.7% had severe symptoms (Canadian Cardiovascular Society [CCS] angina class III-IV) and as much as 37% had no angina plus another 15% in CCS I. Therefore, the randomized population was extremely heterogeneous. Furthermore, data on LV volumes were not reported, except for the substudy on myocardial viability (601 patients) showing an LVESVI of 92 ± 39 mL/m². According to these baseline characteristics, the results of Hypothesis 1 were not surprising: in the literature, no benefit of any type of revascularization in patients with

no angina and enlarged dysfunctional left ventricles has been reported.

Along with the results of the Hypothesis 1 group, data obtained in a substudy of patients randomized to medical therapy with or without CABG after the assessment of myocardial viability were reported.¹⁴¹ There was no significant interaction between viability status (assessed using single-photon-emission computed tomography, dobutamine echocardiography, or both) and treatment assignment with respect to mortality ($P = 0.53$). These results differ markedly from results of previous retrospective studies and meta-analyses, suggesting that assessment of myocardial viability alone should not be the deciding factor in selecting the best therapy for these patients. Future prospective studies need to be designed to determine the role of cardiac imaging in clinical decision making.

Mitral Repair

Ischemic MR conveys an adverse prognosis, doubling the mortality seen in patients after an MI, in those with chronic heart failure, and after surgical or catheter revascularization.¹⁴²⁻¹⁴⁷ It is common, and it increases mortality even when it is mild,¹⁴³⁻¹⁴⁵ with a graded relationship between severity and reduced survival. Currently, it is not clear whether the poorer outcomes in this group depend on the valvular dysfunction or whether it is merely a surrogate marker of extensive comorbidities, particularly the amount of ventricular dysfunction.

The term *functional MR* broadly denotes abnormal function of normal leaflets in the context of impaired ventricular function; it typically occurs in globally dilated and hypokinetic ventricles or with segmental damage that affects valve closure. It occurs in roughly 20% to 25% of patients followed after MI^{143,145,148,149} and in 50% of those with CHF.¹⁵⁰ The mechanism of MR in end-stage heart failure is multifactorial. Briefly, it is related to changes in LV geometry, with a subsequent displacement of the subvalvular apparatus, annular dilation, and restrictive leaflet motion (class IIIb according to Carpentier's classification),¹⁵¹ which results in coaptation failure.

Recent advances in noninvasive Doppler echocardiography allow reliable assessment of regurgitant volume^{152,153} and of the orifice of MR by combined methods.^{154,155}

Since the turn of the century, laboratory and clinical studies¹⁵⁶ have helped to elucidate the mechanisms that underlie ischemic MR, using several different imaging modalities. These studies have demonstrated that the two key anatomic elements contributing to the development of MR are annular remodeling and disruption of the dynamic anatomic relationship between the subvalvular apparatus and the mitral annulus, which is manifested as systolic tethering of the leaflets into the LV cavity. The extent to which each of these two elements contributes to valvular incompetence varies substantially among individual patients.¹⁵⁷

Although several indices of annular remodeling, including mitral annular area, intercommissural width, and septolateral annular diameter, are readily quantified by standard two-dimensional echocardiographic techniques, methods for quantifying leaflet tethering have not

been standardized. Descriptive geometric indicators derived from single-plane measurements made from two-dimensional echocardiographic studies, such as tenting height and area, have been proposed.¹⁵⁸ Tenting is characterized by insufficient systolic leaflet body displacement toward the annulus, with coaptation limited to leaflet tips, resulting in MR. Unfortunately, these measurements are inherently inaccurate because of the high variability of scanning planes and regional variation in both mitral annular shape and leaflet tenting that develop in conjunction with postinfarction LV remodeling. Recently, three-dimensional echocardiography has been applied to the evaluation of mitral valve morphology and may play a valuable role in the assessment of patients undergoing mitral repair surgery.^{159,160}

The clinical significance of functional MR is frequently underrated because of low murmur intensity and mismatch between severe symptoms and unimpressive regurgitant volume and effective regurgitant orifice. Nevertheless, functional MR is a major component of LV dysfunction, causing pulmonary hypertension and LV volume overload, which in turn potentiates LV remodeling, a major determinant of the outcome of LV dysfunction. Mild and moderate functional mitral insufficiency are also associated with significantly decreased survival in patients undergoing CABG, but whether correction of moderate functional MR at the time of CABG improves outcome has yet to be determined.

Previously, surgical treatment of MR was avoided in patients with heart failure and severe pump dysfunction because of concerns about operative risk and perioperative complications. More recently, with improvement in surgical techniques, surgical mitral annuloplasty for MR in the setting of heart failure has become a more popular treatment option. Bolling and associates have demonstrated the feasibility of mitral valve repair in patients with heart failure by downsizing the annulus using a flexible ring.^{79,161} Their initial results in 48 patients who underwent restrictive mitral annuloplasty showed an early mortality rate of approximately 5% with 1- and 2-year survival rates of 82% and 71%, respectively. Several recent studies have confirmed that early mortality is low (between 5% and 7%); heart failure symptoms, LV size, and EF improve; and intermediate outcome is favorable.^{162,163} However, several studies in patients treated with mitral annuloplasty demonstrated a high recurrence rate (30%) of MR after the 6-month follow-up.^{164,165} In contrast to these results, Bax and coworkers¹⁶⁶ reported no recurrence of MR, and Szalay and associates¹⁶³ reported a recurrence rate of 3% with a mean MR grade of 0.6 at 1-year follow-up. The low recurrence rate in these latter studies may be associated with a more truly restrictive annuloplasty performed in these patients. Of note, the paper by Bax and colleagues showed reverse remodeling at follow-up, especially in patients with an LV end-diastolic diameter of less than 65 mm. However, no randomized clinical trial has yet demonstrated that surgical correction of MR by mitral annuloplasty improves survival or leads to reverse remodeling. Wu and associates demonstrated that there is no clearly demonstrable survival benefit conferred by mitral annuloplasty for significant MR in patients with chronic heart failure.¹⁶⁷

Currently, the use of a stringent restrictive ring, two sizes smaller than the measured size, is advocated to achieve a better leaflet coaptation and possibly to prevent recurrence of MR and promote reverse remodeling.¹⁶¹

There are concerns that correction of MR might decrease LV systolic function as a result of afterload increase caused by closure of a low-resistance runoff into the left atrium. In addition, it has been suggested that undersizing the mitral annulus might affect LV contractility because of increased mechanical tension on the base of the heart.¹⁶⁸ Moreover, according to some authors, restrictive mitral repair might impair diastolic filling, but Bolling and Dion demonstrated that undersizing the annulus leads to acute beneficial geometric changes of the base of the LV, which reduces volume and stress.^{79,166}

Mitral surgery is proposed in selected patients to improve cardiac function. However, often in patients with a dilated heart and severe MR, the simple correction of the mitral valve might not be sufficient to improve LV function and reverse LV remodeling. Functional MR is a ventricle disease, and a procedure on the left ventricle should be added whenever possible, especially in ischemic dilated cardiomyopathy. However, if MR is mild, SVR can be used to reduce it by improving LV function and geometry, without surgical valve correction.⁷⁸

Different techniques were reported for reducing the mitral annulus. Kay and colleagues¹⁶⁹ reported mitral plasty with reduction of the posterior annulus without a ring, and Carpentier¹⁷⁰ used a rigid ring. A flexible ring could be also used. Menicanti and associates⁷⁷ reported that the transventricular approach for MR with LV reconstruction could be performed without a prosthetic ring, and that the results were favorable. Bolling and coworkers⁷⁹ used undersized circumferential rings to reduce the annulus in patients with severe MR associated with dilated cardiomyopathy. Isomura and coworkers used noncircumferential flexible rings initially and then changed the technique to use the circumferential semi-rigid rings (Carpentier-Edwards physio-ring) of a smaller size (undersized ring, 26 or 28 mm).¹⁷¹

SVR with or without an intraventricular patch is the second key component of mitral repair. Because reducing ventricular volume decreases wall stress and enhances remote regional wall motion,³² we hypothesize that SVR-related improvement of inferior wall motion is a component of MR reduction. This enhancement, together with reduced papillary muscle width, helps reduce stress and improve remote motion.

However, although our understanding of ischemic MR evolves and the technologies used to manage these patients continue to be refined, the higher rates of recurrent MR after repair have led some to consider valve replacement instead of repair. Evidence for repair or replacement was limited until the released results from the first multicenter, randomized trial, which showed no significant difference in LV reverse remodeling or survival at 12 months between patients who underwent mitral valve repair and those who underwent mitral valve replacement.¹⁷² Replacement provided a more durable correction of MR, but there was no significant between-group difference in clinical outcomes. A longer follow-up is needed to confirm the findings of this trial.

SUMMARY

In the current clinical practice, the choice to add SVR to CABG should be based on a careful evaluation of patients, including symptoms (heart failure symptoms should be predominant over angina); measurements of the LV volumes; careful assessment of mitral valve, including geometry and MR severity; and assessment of the transmural extent of myocardial scar tissue and viability of regions remote from the scar, and it should be performed only in centers with a high level of surgical expertise. Further clarifications of (1) ventricular properties associated with better hemodynamic effects of SVR and (2) links between hemodynamic effects and clinical outcomes could help define appropriate patient selection criteria.

SUMMARY

Heart failure (HF) is a burgeoning disease. Recently published American Heart Association projections indicate that its prevalence will increase by 46% from 2012 to 2030 resulting in approximately 8 million people with HF in the United States alone.¹⁻⁴ Ischemic heart disease is the major contributor to HF and despite best practices and management strategies, many patients are left with significant disability. Events such as myocardial infarction can result in the irreparable loss of viable cardiac mass and in this and many other clinical scenarios, save for transplantation, no therapies currently exist to remedy lost myocardium. Considering the shortage of donor hearts, a rationale to develop regenerative stem cell based therapies is provided.

Thousands of clinicians and investigators worldwide are working toward harnessing the properties of adult stem or progenitor cells to treat injury in tissues and organs that have limited intrinsic capacity for repair and regeneration, such as the brain and the heart. Yet, achieving cellular cardiomyoplasty remains elusive. As a basic definition, cell therapy for regeneration is the therapeutic use of a cell population to promote growth and repair of diseased and / or damaged tissue to restore anatomy and function. The focus tends to be, typically, in settings where this does not occur appreciably such as myocardial infarction and traumatic brain or spinal cord injury. In the setting of ischemic cardiomyopathies, the goal of stem cell therapy would, preferably, be a combination of

promoting the growth of new or existing blood vessels to improve tissue perfusion, and the growth of new cardiomyocytes within the damaged myocardium. Since its inception, cell therapy has achieved the most success in facilitating new blood vessel formation via either angiogenesis or vasculogenesis. Unfortunately, it has been somewhat more difficult to restore lost cardiomyocytes. Although we are likely still decades away from completely regenerating the diseased myocardium, recent evidence indicates that we are at least a little farther ahead. The aim of this chapter is to familiarize readers with the field of cell therapy for cardiac regeneration. Despite many deserving preclinical and clinical studies, unfortunately this review will not be comprehensive, because of length restrictions. Instead, only those cell types with the most promise and best available evidence will be discussed. The clinical focus will be acute MI where the loss of cardiomyocytes is a hallmark of this disorder; however, stem cell use in other clinical entities will also be briefly touched upon. Methods of administration will be covered, as well as the principal mechanisms of action that have been identified. Finally, a brief section will outline some of the current challenges facing the field and possible future directions. At the end of this chapter readers will be familiar with the field of cell therapy for cardiac repair and for those interested references are provided.

DELIVERY METHODS FOR CELL TRANSPLANTATION

Stem cell products for the injured heart can be administered through several methods—some more invasive than others—and each presenting with unique advantages and disadvantages (Table 101-1). Generally, stem cells can be infused intravenously or via patent coronary arteries supplying the ischemic region of the heart, or stem cells can be injected directly into the ventricular wall via a percutaneous transendocardial or a surgical transepicardial approach (Fig. 101-1).

TABLE 101-1 Administration Models

Routes	Advantages	Disadvantages
Intravenous injection	Simplest	Few migrate into the target
Intracoronary injection	Can be administered into patent artery, higher cell homing versus intravenous infusion, low risk of arrhythmia	Unsuitable for larger stem cells, hinder cellular transmigration, exacerbation of atherosclerosis
Intramyocardial injection	Most reliable under direct visualization; highest cell dose	Invasive, potential for cell “clumping”

Intravenous Infusion

Intravenous infusion is the simplest method of cell administration. Given this delivery strategy is nonspecific, it relies heavily on proper homing of the infused cells to the ischemic myocardium. Thus, the disadvantage of this method is that a low percentage of the infused cells home it to the intended target.⁵ Cells can also become trapped in other organs, particularly in lymphoid tissues, so that an additional small proportion of cells enters the coronary circulation and migrates into ischemic myocardium.^{6,7} This is particularly disadvantageous with pluripotent cells increasing the opportunity for off-site proliferation. In addition, with larger cell types, such as mesenchymal stem cells (MSCs) or skeletal myoblasts, microembolization can occur because these cells may be incapable of penetrating beyond a given capillary bed, making them unlikely to reach their target.

Intracoronary Infusion

Infusing stem cells via a patent coronary artery can be performed at the time of selective coronary angiography, and it is well-suited for the specific delivery of cells to the ischemic territory of the myocardium. The obvious advantage of intracoronary infusion is that cells can travel directly into myocardial regions in which nutrient-rich blood flow and oxygen supply are preserved, ensuring a favorable environment for the survival of cells, a prerequisite for stable engraftment.^{8,9} Indeed, in a study performed by Hofmann and colleagues,⁶ homing of unselected bone marrow cells to the infarct region was apparent only after intracoronary delivery but not after intravenous infusion. One disadvantage; however, is that high coronary flow after stem cell injection can prevent low-affinity adhesion to the myocardial capillaries, thus hindering cellular transmigration into the infarcted zone. Another disadvantage to delivering stem cells in this fashion to a potentially diseased segment of the coronary artery is that the combination of stem cells and the pro-angiogenic milieu of the plaque may serve to exacerbate macrovascular and microvascular disease. Similar to intravenous delivery, intracoronary infusion of cells might not be suitable for certain types of larger stem cells, such as skeletal myoblasts and MSCs, which can be prone to embolization. Despite some of these limitations, intracoronary injection of stem cells has been the preferred method of delivery in most clinical studies thus far.

Intramyocardial Injection

Intramyocardial injections constitute an invasive approach to delivering therapeutic cell products compared with the other methods mentioned. This approach is performed by delivering cell suspensions into target myocardial areas via direct injection during minimally invasive thoracoscopic or open procedures.¹⁰ It can be the preferred method of delivery particularly when there is a lack of patent coronary arteries supplying the ischemic region or when the procedure is performed in tandem with mechanical revascularization. The surgical injection process is simple and can be performed under direct

FIGURE 101-1 ■ Delivery routes for transplanted cells for the treatment of ischemic heart disease.

visualization, allowing evaluation by inspection of the potential target zones. As an alternative to user-based visualization of cell injection, electromechanical mapping (e.g., using the NOGA system) can serve to improve the reliability of surgical transeptal injections, or assist transcatheter injections as a percutaneous procedure.¹¹ Multiple injections of concentrated cell suspensions at minimal volumes appear preferable to less frequent, larger volume injection. This method is feasible and potentially the most reliable in ensuring stem cells reach the intended or injured areas of the myocardium.⁸ Regardless, it is still difficult to predict the survival and function of progenitor cells injected into uniformly necrotic tissue, and the ischemic or necrotic area may prove too hostile to ensure proper cell engraftment and survival.

There are disadvantages to intramyocardial injections. Some nonspecific delivery can occur often because of cell leakage during injection. Moreover, cell clumping can prevent uniform cell distribution in the target area. This method of delivering stem cells may also be inappropriate in situations of diffuse disease such as nonischemic dilated cardiomyopathy where focal deposits of directly injected cells might be poorly matched to the underlying pathophysiology.¹²

Summary

The optimal route for administering stem cells has yet to be determined, although the method of choice will likely be specific depending on a number of factors such as the cell product, patient clinical characteristics, and disease setting. In more acutely ischemic scenarios such as acute myocardial infarction (AMI), the release of chemotactic stimuli into the peripheral circulation, in response to the ischemic injury, may favor homing of intravenous or intracoronary infused cells. However, in situations in which these signals have been abated, as may be the case for chronic ischemia or old scar, injection of the cells directly into the cardiac muscle may produce a more favorable outcome.¹³ To date, most trials report a low frequency of complications regardless of route of administration associated with cell base therapies supporting the safety of any of these approaches.¹⁴

ADULT STEM OR PROGENITOR CELLS FOR CARDIAC CELL THERAPY

A number of adult stem or progenitor cell types have been investigated for the treatment of heart disease

FIGURE 101-2 ■ Cell types currently undergoing clinical trial and emerging cell types. EPC, Endothelial progenitor cell; HSC, hematopoietic stem cell.

(Fig. 101-2). They have been procured from the bone marrow (bone marrow–derived mononuclear cells [BMCs]), the peripheral circulation, adipose tissue, skeletal muscle, or cardiac muscle biopsy specimens. Pluripotent cells such as the embryonic stem cell (ESC) or the inducible pluripotent stem cell (iPSC) have also received much attention. Most have been investigated extensively in preclinical models, and some in the clinical arena. Some emerging cell types, such as the iPSC, have not yet reached clinical trial. The most pertinent cell types, either for emerging relevance or historical importance, are discussed in the following sections, and a summary is provided in Table 101-2. No consensus has been reached on the ideal cell type; however, some candidates appear more promising than others. If the ideal cell type does exist, it should fulfill most if not all the following criteria¹⁶⁶:

1. Stem cells should be safe. In other words, they should not form tumors, predispose patients to fatal arrhythmias, or elicit immune reactions.
2. Stem cells should improve heart function, quality of life, and mortality.
3. Stem cell harvest and culture methods should be clinically feasible and not cost-prohibitive.
4. Stem cells should be available as a standard, “off-the-shelf” product.

5. Stem cell use should not be controversial or ethically ambiguous.

The following sections will cover the predominant cell types emphasizing clinical data. For emerging cell products that have not yet reached clinical trial, animal studies instead will be the focus. A summary of select clinical trials is provided in Table 101-3 (note that this table is not exhaustive, but is provided as an example).

Bone Marrow–Derived Cells

The bone marrow hosts a myriad of cell populations, including hematopoietic and nonhematopoietic cells and progenitors. Interest in autologous BMCs for the treatment of ischemic cardiac syndromes was first stimulated by the discovery of the putative endothelial progenitor cell (EPC) by Asahara and colleagues in 1997.¹⁵ These EPCs, originally from the bone marrow, were found to circulate in the peripheral blood homing to sites of tissue ischemia to participate in postnatal vasculogenesis.¹⁵ Since then, cells derived from the bone marrow have been the preferred cell type in both preclinical and clinical cardiac cell therapy studies. BMCs can be harvested via either bone marrow aspiration or peripheral blood apheresis followed by isolation of the

TABLE 101-2 Cell Types

Cell Type	Phenotypic Markers	Advantages	Disadvantages
Skeletal myoblasts	CD56, Desmin	Easily harvested and expanded; good survival rates; differentiate into myotubes	Poor differentiation into cardiomyocytes; high risk for arrhythmias
Embryonic stem cells	CD133, Oct 4, SSEA-3/4, Sox	Differentiate into cardiomyocytes, endothelial cells, and smooth muscle cells	Ethical challenges, tumorigenicity, ectopic differentiation, immunogenicity
Bone marrow–derived stem cells			
Hematopoietic stem cells	CD34, CD133, CD45, Sca-1, c-kit	Improve cardiac function, promote angiogenesis	Mechanistically, may only reconstitute peripheral blood leukocytes
Endothelial stem cells	CD34, CD133, VEGFR2, CD144, Sca-1	Increase blood vessel formation, prevent cardiomyocyte apoptosis	Variable efficacy
Mesenchymal stem cells	CD106, c-kit	Have reduced immunogenicity (at least initially), easy to expand and maintain ex vivo; robust secretome	Large cell type
Adipose tissue–derived cells		Less expensive, less invasive to harvest, and potentially available in great quantities	Isolation needs to be optimized for clinical use
Side population cells	CD45, CD59, CD43, CD49d, CD31, and integrin markers	Differentiate into cardiomyocytes and endothelial cells	Little if any preclinical data
Inducible pluripotent cells	Oct4, Sox2, Klf4, c-Myc, Lin28, Nanog (introduced)		Yet to be tested
Cardiac stem cells	c-kit, Sca-1, isl 1	May generate cardiomyocytes; strong paracrine repertoire	Very low numbers, isolation difficult; limited clinical experience

mononuclear cell fraction by density-gradient ultracentrifugation. Upon isolation of the mononuclear fraction, BMCs can either be kept unfractionated or be further purified to isolate subpopulations identified by specific surface antigenic expression. In some cases, depending on desired cell type, fractionated BMCs may require further ex vivo expansion in culture.⁸ The subpopulations of BMCs that have been studied in the context as cardiac regenerative therapies includes hematopoietic stem cells (HSCs), EPCs, MSCs, and purified CD133⁺ or CD34⁺ cells (see Fig. 101-2). Bone marrow products have gained much favor from investigators mainly because of their ease of procurement and expansion in culture, and they tend to possess a relatively high concentration of adult progenitors.⁸

Unfractionated Bone Marrow Cells

The capacity for unselected or unfractionated BMCs to promote cardiac repair has been controversial,¹⁶⁻¹⁸ yet they remain the most thoroughly investigated cell type in clinical trial.¹⁹ Their popularity is driven largely by practical reasons. For example, BMCs are (1) derived from straightforward harvest protocols, (2) do not require complex or prolonged ex vivo management, and (3) contain a small niche of stem and progenitor cells despite representing a heterogeneous population.¹⁹ BMCs have been investigated in AMI, chronic ICM, and HF, but for the sake of brevity the following section will focus on trials of AMI. Readers interested in the results of BMC therapy in other clinical settings can consult several excellent reviews.^{10,19}

The safety and feasibility of BMC therapy was established from early, small trials of AMI such as the “Transplantation of Progenitor Cells and Regeneration Enhancement in Acute Myocardial Infarction” (TOPCARE-AMI).²⁰⁻²² The demonstration that cell therapy may be safe, and possibly effective, prompted further inquiry into mid-sized, double-blind, randomized trials such as the “Reinfusion of Enriched Progenitor Cells and Infarct Remodelling in Acute Myocardial Infarction” (REPAIR-AMI) and the “BOne marrow transfer to enhance ST-elevation infarct regeneration” (BOOST) trials.^{23,24} Initial follow-up analysis from both the REPAIR-AMI and BOOST trials reported benefits associated with BMC therapy.^{23,24} BMCs were infused 3-7 days after successful reperfusion and were associated with superior cardiac function (5.5%-6.7% improved left ventricular ejection fraction [LVEF]) compared with placebo at 6 months postintervention.^{23,24} In addition, cell therapy was not associated with an increased risk for adverse clinical events.²⁴⁻²⁶ Substudies of both trials were subsequently released by trial investigators with equally promising results. For example, patients receiving BMCs in BOOST demonstrated improvements in diastolic function,²⁷ whereas there was a reduction in a prespecified cumulative end-point of death, MI, or necessity for revascularization at 1-year follow-up of the REPAIR-AMI.²⁶ Several other trials also support the benefit of BMC therapy in patients with AMI. Trials by Assmus and colleagues,²⁸ Cao and colleagues,²⁹ Yousef and colleagues,³⁰ and the “FINish stem CELL study” (FINCELL) reported positive benefits associated with BMC therapy including improved global ventricular function, a reduction in

AMI, Acute myocardial infarction; BMC, bone marrow–derived mononuclear cell; CDC, cardiosphere derived cells; CMI, chronic myocardial infarction; CPC, circulating progenitor cell; CTO, chronic total occlusion; EF, ejection fraction; EPC, endothelial progenitor cell; ESV, end-systolic volume; G-CSF, granulocyte colony-stimulating factor; HF, heart failure; IC, intracoronary; IM, intramyocardial; LV, left ventricular; MSC, mesenchymal stem cell; RA, refractory angina pectoris.

morbidity and mortality, and a neutral effect on severe adverse reactions, including arrhythmias and restenosis of the stented coronary artery.²⁸⁻³¹

Unfortunately, despite the positive early experience with BMCs in patients, other trials have not been so promising. Moreover, follow-up from some of the earlier, positive trials were beginning to release disappointing long-term results. For example, the 2-year results of the REPAIR-AMI could not conclusively associate BMC therapy with improved morbidity and mortality²⁸; in BOOST, whereas the difference in LVEF improvement between cell therapy and placebo were significant at 6-month follow-up, the effect was not sustained at 18 months.^{24,32} A subgroup of patients with pronounced transmural infarcts may have benefited from cell therapy, although this was required to be tested prospectively in a randomized trial. Regardless, the lack of beneficial effects associated with BMCs in BOOST was sustained in the 5-year results.³³ Examples of results from recent trials include the “BONE marrow in Acute Myocardial Infarction” (BONAMI), which have been mixed, and those from the “Autologous Stem-Cell Transplantation in Acute Myocardial Infarction” (ASTAMI) trial, which were altogether negative.^{34,35} Aside from a small improvement in exercise time, ASTAMI did not associate BMCs with improvements in global LV function, or ventricular remodelling.^{34,36-38}

Before reaching clinical trial, many elements such as cell dose, frequency, or time of delivery had not been systematically determined for stem cell therapies. In some trials, such as the REPAIR-AMI, only until patients were stratified based on time of delivery after reperfused MI did some suggestion arise that timing of delivery influenced the efficacy of the therapy. This prespecified subgroup analysis associated later cell delivery (about 7 days after reperfused MI) with more pronounced benefits.²³ Thus, several recent trials including the TIME, late-TIME, and SWISS-AMI sought to test this hypothesis comparing the time of delivery between cells delivered early, mid, or late postinfarction.³⁹⁻⁴² Unfortunately, results from all three trials did not associate beneficial

effects with BMC therapy for AMI, consistent with the BOOST and ASTAMI trials, regardless of when cells were delivered after AMI.³⁹⁻⁴² Results from the TIME trial may, however, require careful scrutiny as cells were procured from a novel, convenient extraction method that had not been previously validated in bioactivity assays or animals models as opposed to the already well-supported and published methods for isolation.

Establishing a concrete position on the efficacy of BMC therapy for AMI has so far been difficult and results from recent trials such as TIME, late-TIME, or SWISS-AMI have not been able to answer this question conclusively. The outlook for BMC therapy is less than optimistic. Given the conflicting evidence and emerging alternatives, favor may lean toward products with well-demonstrated capacity to produce improvements in global LV function, mortality, and quality of life. Moreover, although some cumulative evidence from recent meta-analyses suggests that BMCs are associated with modest improvements in LV function (2%–4% LVEF), the question remains of whether these improvements are clinically meaningful.^{43,44} The upcoming European large, phase 3 “Effect of Intracoronary Reinfusion of Bone Marrow–derived Mononuclear Cells on All-Cause Mortality in Acute Myocardial Infarction” (BAMI) trial (NCT01569178) will probably represent the final consensus of BMCs in cardiac cell therapy in AMI.

Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are a subset of BMCs that are multipotent and self-renewing and from which all blood cell types are derived. They are possibly the first stem cell therapeutic investigated in patients dating back from early trials of bone marrow transplantation for fatal leukemias.⁴⁵ Their use can be potentially curative for genetic blood disorders such as thalassemia and immune deficiency, or malignancies such as leukemia.⁴⁵ The prevailing hypothesis is that HSCs give rise to two lineage restricted progenitor cell types, including myeloid progenitors and lymphoid progenitors that, in turn, supply

the number of lymphocytic and granulocytic cells, macrophages, platelets, and erythrocytes found in the blood. However, specific identification and classification of HSCs has been difficult largely because of the limitations of current imaging and lineage tracing methods.⁴⁶ Generally, HSCs are identified by a lack of hematopoietic or myeloid lineage (lin) markers and, depending on the report, the presence of a number of antigenic surface markers such as CD34, CD38, CD90, CD133, CD105, CD45, and c-kit (CD117) or other markers such as the presence of aldehyde dehydrogenase.^{47,48} Their use as a cardiac regenerative cell product was stimulated by early studies indicating that lin⁻, c-kit⁺ HSCs could restore necrotic myocardium by transdifferentiating into all the major cardiac cell types (cardiomyocyte, endothelial cell, and smooth muscle cell) conferring salutary effects.^{49,50} Unfortunately, this notion was met with sharp criticism and conflicting data.^{16,17} Subsequent evidence instead indicates that HSCs are, in fact, not cardiomyogenic but adopt mature hematopoietic fates in ischemic myocardium.^{16,17,51} Whether the benefits of HSCs are derived from an ability to restore damaged myocardium or from a separate, possibly paracrine, mechanism remains a topic of intense debate.⁵⁰

Consensus on what combination of surface, cytosolic, or functional markers define the HSC is lacking, thus making direct comparisons between trials difficult. Given this loose definition of HSCs, some of the trials discussed in the following section might apply equally to other BMC products, and vice versa. The MAGIC trial assessed the feasibility and efficacy of HSC infusion in patients with MI and who underwent coronary stenting.⁵² Granulocyte colony-stimulating factor (G-CSF), a well-established stem-cell mobilizer, was administered to mobilize bone marrow-derived HSCs into the peripheral blood 4 days before apheresis and cell procurement.⁵² This trial involved three separate arms including the HSC group, a control group (not placebo), and patients receiving G-CSF alone.⁵² At 6 months after infusion, patients treated with HSCs showed significant improvements in exercise capacity (450 vs. 578 seconds), myocardial perfusion (perfusion defect, 11.6% vs. 5.3%), and systolic function (LVEF, 48.7% vs. 55.1%). Although no adverse events occurred because of cell infusion combined with G-CSF, enrollment of the G-CSF cohort was eventually discontinued because of high rates of in-stent restenosis, highlighting a potential safety concern and cautioning future trials using G-CSF administration as a strategy for endogenous stem cell mobilization.⁵² Recent trials, though, such as Perin and colleagues⁴⁷ have not reported any significant adverse cardiovascular or cerebrovascular events associated with HSC infusion in similarly high-risk patient cohorts with advanced ischemic heart failure and CAD ineligible for PCI or surgical revascularization.⁴⁷ The difference, perhaps, is that Perin and colleagues⁴⁷ elected to aspirate bone marrow from the iliac crest as opposed to administering G-CSF. In their trial, HSCs were then purified based on the presence of cytosolic ADH, constituting a population of primitive Lin⁻CD34⁺CD38⁻ cells. When administered to patients with advanced ischemic heart failure ADH⁺ HSCs were associated with a significant decrease in

left-ventricular end-systolic volume and a trend toward maximal oxygen consumption at 6 months.⁴⁷ It is difficult to draw meaningful conclusions given that only 20 patients were enrolled in the study. Overall, HSCs appear to be beneficial for the treatment of ischemic cardiomyopathies, but larger, randomized, controlled trials are required to confirm early results.

Endothelial Progenitor Cells

Before the characterization of a circulating EPC in 1997 by Asahara and colleagues,¹⁵ vasculogenesis, the process of de novo blood vessel development, was believed to be limited to the embryonic development of vasculature from endothelial cell progenitors or angioblasts. Now it is understood that a subset of bone marrow cells, possibly the putative EPC, mobilizes from the bone marrow to the peripheral circulation ultimately reaching sites of tissue injury or ischemia to participate in postnatal vasculogenesis.^{13,15,53,54} Circulating EPC levels have also been recognized as possibly providing clinical information on atherosclerotic burden and future cardiovascular risk.^{55,56} Despite the significant attention that has been devoted to studying EPC biology, consensus on an unambiguous definition of the EPC is still lacking and, likewise, the success of many studies has been hindered by the absence of such a definition. EPCs were first characterized as a population of cells that were CD34⁺, VEGFR2⁺, and adherent to fibronectin (Fig. 101-3A).¹⁵ Today, they are either broadly identified as the mononuclear cells adherent to fibronectin or by cell surface expression that may or may not include CD31, FLK-1 (VEGFR2), CD34, CD133 (AC133), c-kit, and other endothelial markers including VE-cadherin.⁵⁷ The criteria that distinguish an HSC from an EPC, and vice versa, may seem unclear given they seem to share many of the same surface antigenic markers.⁵⁷ As a cell therapy product, however, EPCs are distinguished from HSCs based on specific ex vivo culture requirements. Separate techniques exist to produce what can be referred to as the *early* or *late* EPC. Both early and late EPCs first require isolating the mononuclear cell fraction from the peripheral circulation, and early EPCs are generated

FIGURE 101-3 ■ Endothelial progenitor cells (EPCs) and mesenchymal stem cells (MSCs) in culture. **A**, EPCs from the peripheral blood mononuclear cell layer, cultured on fibronectin for 4 days. Adherent cells (CD34⁺, VEGFR-2⁺) typically take up the markers lectin and Dil-Oxidized Low Density Lipoprotein. **B**, MSCs cultured from human bone marrow yielding a population of adherent MSCs that characteristically express the antigens CD29 and CD44 but are negative for the hematopoietic cell marker CD45.

through subsequent culture on fibronectin for 3 to 7 days, whereas late EPCs are produced via culture for greater than 14 days on collagen type I.^{55,58} For a more detailed discussion on the characterization of EPC phenotypes or potential diagnostic use of circulating EPCs, interested readers are referred to an excellent review by Fadini and colleagues.⁵⁵

In preclinical animal models of ischemic cardiomyopathy EPC transplantation prevented cardiac myocyte apoptosis, resulted in increased blood vessel formation, decreased infarct size, and improved function.^{59,60} The capacity for human EPCs to transdifferentiate into cardiomyocytes has also been reported,⁶¹ but not all studies support this conclusion.⁶² Instead, recent evidence suggests that human early EPCs may be proangiogenic, enacting their salutary properties through paracrine mechanisms. The proangiogenic effects of late EPCs, instead, is thought to be via direct incorporation into the vasculature.^{55,63}

Considering the attention EPCs have received in preclinical animal models of myocardial ischemia, there is comparatively little experience with their use in patients. This is likely owing to pragmatic considerations and investigator preference for unfractionated or sorted BMC products neither requiring ex vivo culture. EPC cell therapy has been explored in several settings, including AMI and chronic ischemic heart disease. As a therapy delivered shortly after reperfused AMI, the small TOPCARE-AMI trial reported that EPC transplant was safe, feasible, and potentially beneficial.²⁰ EPCs were infused approximately 4 to 5 days after MI and were associated with improved LVEF ($51.6 \pm 9.6\%$ to $60.1 \pm 8.6\%$), improved regional wall motion in the infarct zone, and profound reduction in end-systolic left-ventricular volumes at 4-month follow-up,²⁰ with benefits persisting in the final 1-year follow-up.²² Indeed, contrasting results were released by the same group in a similar trial assessing EPC cell therapy for the treatment of chronic ischemic heart disease.⁶⁴ The randomized, controlled TOPCARE-CHD trial assessed the efficacy of BMC, EPC, or placebo treatment later after MI in patients who had a myocardial infarction at least 3 months before enrollment and a well-demarcated region of left ventricular dysfunction.²⁰ Cells were infused into the vessel supplying the most dyskinetic area of the ventricle, and the results of this study contradict those of TOPCARE-AMI, as EPC delivery was significantly inferior to BMC therapy in terms of improving global left ventricular function.⁶⁴ The absolute improvement witnessed with BMC therapy, similar to their experience in AMI, was modest. BMC therapy was associated with an increase in approximately 2.9 percentage points according to left ventricular angiography and 4.8 percentage points according to MRI.⁶⁴ The precise mechanisms underlying the benefit of BMC therapy were not investigated in the trial, and it remains unclear as to why EPCs proved inferior in this setting. A higher number of progenitors isolated from the bone marrow aspiration may account for this discrepancy. Moreover, given that patients with CHD have been shown to have pronounced EPC dysfunction, limited cell recruitment and action at the site of injury may have also contributed.⁶⁵

Fractionated CD34⁺ Bone Marrow Cells

As an alternative to heterogeneous cell products, in recent years focus has shifted to BMCs isolated based on CD34 expression given their potent proangiogenic properties.⁶⁶ CD34 is believed to be a cell-to-cell adhesion factor expressed in some cell types, including hematopoietic cells, endothelial cells, muscle satellite cells, hair follicle stem cells, and fibrocytes.⁶⁷ The function of CD34 remains largely unknown, although in HSCs some evidence suggests that CD34 alters engraftment potential and other properties, such as cell adhesion and migration.^{67,68} Peripheral blood CD34⁺ cells have been shown to transdifferentiate into most of the major cardiac lineages,⁶⁹ including endothelial cells,^{15,70} vascular smooth muscle cells,⁶⁹ and cardiomyocytes,⁷¹ principally via cell fusion.⁷² CD34⁺ cells purified from peripheral blood BMCs have been shown to exhibit superior efficacy and safety for therapeutic neovascularization after MI compared with total mononuclear cells in rodent studies.^{59,60,73} They have also been shown to exhibit superior efficacy for preserving integrity and function following MI compared with unselected mononuclear cells with an equivalent number of CD34⁺ cells,⁷³ suggesting that a purified CD34⁺ cell product might possess greater therapeutic potential than a mixed mononuclear cell population.

The REGENT trial investigated the therapeutic potential of fractionated CD34⁺ mononuclear cells for the treatment of significant systolic dysfunction (LVEF < 37%) secondary to reperfused anterior MI.⁷⁴ Two hundred patients were randomized to intracoronary infusion of CD34⁺CXCR4⁺ purified cells, total mononuclear cells, or a control group receiving no therapy at all (no placebo) and were followed for 6 months.⁷⁴ Similar to REPAIR-MI, both the purified CD34⁺CXCR4⁺ and BMC therapies were associated with a trend in modest improvement ($\approx 3\%$) in systolic function.⁷⁴ Unfortunately, the study was plagued by a high dropout rate in the control cohort, probably because of the open-label design, which may have potentially accounted for some results not reaching statistical significance. Nonetheless, for patients who received CD34⁺ cell therapy, a clear trend for better outcomes was evident in patients with a baseline ejection fraction (EF) below the median (<37%) compared to those whose baseline EF was above the median. In addition, a low baseline EF (<37%) was an independent predictor for pronounced benefits in terms of cardiac function.⁷⁴ This pattern is consistent with the results reported in REPAIR-AMI.²³ The authors also highlighted that the use of a relatively small number of CD34⁺CXCR4⁺ cells was associated with a similar trend in functional improvement as the use of 100 times more total mononuclear cells, similar to the results published by Kawamoto and colleagues in rats.^{73,74} The mechanisms that could account for these benefits were not explored, but it is unlikely that it was a result of de novo cardiomyocytes. Instead, recent laboratory evidence indicates that CD34⁺ cells secrete exosomes that have independent angiogenic activity, potentially accounting for a significant component of the paracrine effect of these cells.⁶⁶

Indeed, the hallmark of ischemic cardiomyopathies, such as myocardial infarction, is the loss of myocardium.

In this scenario, cell therapy may be a futile endeavor if no meaningful restoration of myocardium can be accomplished. Moreover, the data supporting the cardiomyogenic potential of CD34⁺ purified cells is less than convincing. However, in situations in which instead neovascularization may be preferred, CD34⁺ cells could offer some benefit. Early evidence for the feasibility, safety, and benefit of purified CD34⁺ cells mobilized by G-CSF administration in 24 patients with refractory angina was provided by Losordo and colleagues⁷⁵ in a pilot phase I/IIa randomized trial. Follow-up was performed in a larger double-blind, randomized phase II trial in 167 patients.⁷⁶ CD34⁺ purified cells, or an equal volume of diluent (placebo), were injected with an electromechanical (NOGA) mapping injection catheter. Low-dose CD34⁺ therapy improved both weekly angina frequency and exercise tolerance measures.⁷⁶ Mortality was not different between control and cell therapy cohorts at 12 months, although cell mobilization and collection procedures were associated with elevations in cardiac enzymes that will require follow-up in future studies.⁷⁶

CD34⁺ purified cells might represent a natural progression from unfractionated BMC therapies, and a more standard product compared with HSC- or EPC-based therapies based on their properties and preclinical results. However, cumulative evidence reviewed in a recent meta-analysis of BMC trials suggests that, overall, CD34⁺ purified cell therapy might not offer meaningful benefits in the settings of acute MI or chronic HF, possibly because of a lack of clinically relevant cardiomyogenic potential.⁴³ Given their potent proangiogenic paracrine properties, CD34⁺ cells could offer potential in settings where neovascularization in itself could offer substantial benefits, such as refractory angina or chronic ischemic cardiomyopathy.

Mesenchymal Stem Cells

Mesenchymal stem cells are stromal cells found within the bone marrow or adipose tissue and can be expanded via ex vivo culture (see Fig. 101-3B).⁷⁷ Similar to other bone marrow cell types, they are loosely defined based on surface expression and culture characteristics which include adherence to plastic in cell culture and the surface antigen expression of CD105⁺/CD90⁺/CD73⁺/CD34[−]/CD45[−]/CD11b[−] or CD14[−]/CD19[−] or CD79[−] α /HLA-DR1[−].⁷⁸ MSCs have been identified as promising candidates because of their relative ease of procurement, multilineage differentiation potential, robust secretome, antiapoptotic, immunomodulatory properties.^{55,81,83,84} They have also been shown to be capable of activating resident cardiac stem cells.^{51,77,79,80} Given their immune-privileged status, they may serve as ideal allograft candidates, although the long-term benefits as allogeneic products have been challenged.⁸¹ Some authors contend that MSCs can adopt cardiomyocyte-like phenotypes when injected into both healthy and infarcted myocardium; however, these results have been scrutinized, and others attribute these observations as either MSC fusion with resident cardiomyocytes or nonexistent altogether.^{79,82,83}

Purified human-derived MSCs have been shown to attenuate contractile dysfunction and to prevent adverse

remodeling in rodent and swine models of myocardial infarction.⁸²⁻⁸⁴ In contrast with the classical method of collecting cells and deploying via infusion or injection, initial clinical attempts at harnessing MSCs assessed pharmacologic mobilization of the cells from the bone marrow using G-CSF. Assessing G-CSF mobilized cells soon after AMI, results from the “G-CSF ST-segment Elevation Myocardial Infarction” (G-CSF STEMI), “STEM cells in Myocardial Infarction” (STEMMI), and “Regenerate Vital Myocardium by Vigorous Activation of Bone Marrow Stem Cells” (REVIVAL-2) trials showed that G-CSF administration did not result in improved systolic function compared with placebo.⁸⁵⁻⁸⁸ A substudy of the STEMMI trial sought to describe the cells mobilized by G-CSF administration and to determine the association, if any, between plasma concentration of these cell types and changes in left ventricular systolic function.⁸⁶ The authors associated an inverse relationship between circulating MSCs and systolic functional improvement following G-CSF administration after MI.⁸⁶ This relationship was left relatively unexplored, but it could be a consequence of several mechanisms. It may be that reduced circulating MSCs is a reflection of increased homing to the infarcted myocardium, or given the large size of MSCs their increased concentration in the circulation may contribute to further microembolization and infarction.

MSCs are one of the few cell types to date that may offer a true “off-the-shelf” product given their potential immune-privileged status.⁷⁸ Hare and colleagues⁸⁹ assessed the safety of this type of allogeneic product in a double-blind, randomized, dose-ranging trial of 53 patients with reperfused MI. The primary end-point of the study was safety, whereas efficacy measured by ejection fraction and ventricular volumes constituted exploratory, secondary end-points. Safety profiles were similar between the allogeneic MSC product (Prochymal; Osiris Therapeutics Inc., Baltimore, MD) and placebo treatments.⁸⁹ Patients receiving MSCs experienced fewer episodes of ventricular tachycardia and improved pulmonary forced expiratory volumes.⁸⁹ In terms of efficacy, MSCs were associated with improved global symptom score and ejection fraction.⁸⁹ These results highlight some potential advantages of MSCs versus other BMC products. For example, the product used in this trial was a readily available allogeneic product prepared from healthy donors, circumventing any potential issues with patient clinical condition on cell potency. It also obviates the need for an invasive and highly painful bone marrow aspiration. Results from the recent POSEIDON trial reinforce some of these benefits.⁹⁰ POSEIDON was a small, randomized, pilot trial that compared the safety and efficacy of autologous or allograft MSC transcatheter delivery in patients with chronic ischemic LV dysfunction secondary to MI.⁹⁰ The primary end-point was safety measured by incidence of severe adverse reactions.⁹⁰ None of the cell products reached the predefined stopping point for incident severe adverse reactions, supporting the low immunogenicity of MSCs. In terms of secondary end-points, reflecting efficacy, the combined results appear encouraging. Autologous, but not allogeneic, therapy resulted in improvements in the

6-minute walk test and Minnesota Living with Heart Failure Questionnaire (MLHFQ) scores.⁹⁰ Moreover, both cohorts demonstrated improvements in New York Heart Association (NYHA) class.⁹⁰ Both were associated with reduced early enhancement defect, a measure of infarct size, end-systolic volumes, and sphericity.⁹⁰ In addition, patients having received allogeneic therapy demonstrated improved end-diastolic volumes.⁹⁰ Changes in EF were not apparent from the aggregate results, although a trend for an inverse dose-response relationship was observed. Increases in EF and pronounced changes in ventricular geometry were evident in patients receiving a lower dose of MSCs.⁹⁰ The results are promising but will require substantiation in several follow-up trials given the small sample size, open-label design, and lack of a placebo-controlled group.⁹⁰

MSCs are an exciting candidate as the field of cell therapy progresses. Given their potent paracrine properties and immune privilege, they may truly offer the potential for an off-the-shelf product. A major knowledge gap that remains before the potential for these cells can be fully realized is the mechanisms underpinning observed benefits. Nevertheless, given their purported benefits and considerable secretome, MSCs appear to be promising as cardiac cell therapy evolves.

Summary of Bone Marrow Cell-Derived Products

Establishing a firm position on the benefits of BMC-based cell therapies is challenging. Several recent meta-analyses agree that BMC cell therapy could offer modest short-term functional improvements at 6 to 12 months, with a trend indicating that these benefits may also persist long term in patients with AMI.^{43,44} Some effects on left ventricular end-systolic volume, recurrent AMI, readmission for heart failure, unstable angina, or chest pain were also associated.^{43,44} Given the high degree of trial variability in elements—such as the time of delivery following MI or reperfusion, cell type, cell dose, method of administration, imaging modalities to assess function, and clinical hard end-points—conclusions are difficult to draw. Moreover, many of the recent, larger trials failed to demonstrate benefits.⁹¹ Even so, the question remains of whether modest improvements in cardiac function are clinically relevant.⁴³ Several of the aforementioned BMC cell types may be suitable for some clinical scenarios, although they likely do not represent the ideal candidate for regenerating lost myocardium.

Pluripotent Cells

The two cell types that may possess the most potential are the ESCs and their manmade counterparts—the inducible pluripotent stem cells (iPSCs)—although the neoplastic risk associated with pluripotent cells may preclude their use in patients. ESCs also remain a controversial cell type given their stage of harvest. ESCs are obtained from the inner cell mass of a preimplantation-stage blastocyst.⁹² They were first successfully isolated in 1998,⁹² and since have been differentiated into cardiomyocytes *ex vivo*.^{93,94} Undifferentiated human ESCs express the stem cell markers Oct4, stage-specific mouse

embryonic antigen (SSEA)3/4, TRA-1-60, and TRA-1-81.⁹⁵ ESC-derived cardiomyocytes exhibit proper morphology with organized sarcomeres and express cardiac specific transcription factors such as Nkx2.5, GATA-4, and MEF2C, although they lack a true, mature phenotype.^{96,97,98} Transplanted ESC-derived cardiomyocytes have been shown to produce functional improvements in several rodent infarct models.⁹⁸⁻¹⁰¹ To date, only one pre-clinical large animal study, performed by Ménard and colleagues,¹⁰² has been conducted to evaluate the cardiomyogenic potential of ESCs for myocardial ischemia. Ménard and colleagues¹⁰² delivered cardiac-committed murine ESCs 2 weeks after MI into the host myocardium of immunosuppressed or immunocompetent sheep. The ESCs engrafted and functionally colonized the scar area, with new cardiomyocytes resulting in modest improvements in cardiac function.¹⁰² ESCs represent the ultimate example of the candidate cell for cell therapy as they fulfill all the criteria of a stem cell: clonality, self-renewal, and pluripotency. However, given they can be driven to virtually any cell type they are also a significant neoplastic risk.¹⁰³ ESCs will also necessarily be allografts posing a risk for graft rejection. The benefits reported by Ménard and colleagues¹⁰² occurred without teratoma formation or graft rejection, regardless of whether the sheep were administered immunosuppression. Others, though, have published contrasting results.¹⁰¹⁻¹⁰⁴ Future methodological breakthroughs may serve to significantly reduce the risk of graft rejection or neoplasticity, although it is contentious whether these risks can be eliminated completely. The modern clinical trial is a stringent and risk-adverse environment, each becoming more and more difficult to achieve regulatory approval.^{3,45} Graft rejection and teratoma formation for ESC therapy, even in one patient, would constitute an unacceptable outcome. It is also doubtful that the controversy surrounding ESC use in the clinic will subside—at least anytime soon. Therefore, it is unlikely, at least for the foreseeable future, that ESCs will ever be used in the clinic.

The iPSC was the focus of the 2012 Nobel Prize in Physiology or Medicine.¹⁰⁵ They were first generated from adult mouse somatic cells using a collection of transcription factors known as *Yamanaka factors*, named after the senior author who led the discovery.¹⁰⁶ The first human iPSCs were generated in 2007 and have since successfully produced cardiomyocytes *in vitro*.¹⁰⁷⁻¹⁰⁹ The iPSC has garnered significant attention in disease modeling,¹¹⁰ and, unsurprisingly, many investigators agree that the iPSC holds tremendous promise for cardiac regenerative medicine.¹¹⁰ At the time of writing this chapter, no clinical trials were in progress relating to iPSC use for cardiac regenerative purposes; however, several animal studies have been published offering promising early results. Canine- and porcine-derived predifferentiated iPSC-endothelial cells were shown to restore cardiac function and to reduce infarct sizes in murine models of myocardial infarction.^{111,112} iPSCs could constitute a viable autologous cell therapeutic, particularly since they obviate the legal and ethical concerns traditionally associated with ESCs. Moreover, as iPSC reprogramming technology improves they may constitute the ideal cell type for personalized medicine. It may be possible one day to design patient- or disease-specific iPSCs in an

effort to cater to specific clinical needs and patient characteristics. Currently, translation of iPSC based therapies into the clinic is premature. For one, similar to ESCs the methods required to produce iPSCs are known to be oncogenic.¹¹³ New techniques have done much in addressing this issue including the use of small molecules or synthetically modified mRNA.^{114,115} Predifferentiating iPSCs to the desired cell type, such as cardiomyocytes or endothelial cells, may be a possible alternative if contaminating undifferentiated iPSCs could be eliminated, or at least significantly minimized.¹¹⁶ Regardless, these efforts may be futile because the process of reprogramming somatic cells can induce genetic or epigenetic aberrations that may prove irreconcilable technically and incompatible clinically.¹¹³ Ultimately, new methods would need to be verified rigorously first to ensure the absence of a neoplastic risk before the first patient could be treated. Should the risk of tumor formation be addressed, the lack of methods to produce standardized cell products with sufficient yield is another obstacle that may also preclude their clinical use.¹¹⁷ The efficiency of generating iPSCs is low, and there is significant variability in yield with current methods and technology.^{113,117} Nevertheless, the results from early studies into the potential therapeutic benefits of iPSC-derived products certainly warrant further investigation.

Cardiac Stem and Progenitor Cells

The premise that the adult human heart is a postmitotic organ was the dominant view for much of the twentieth century. Observations of possible cardiomyocyte turnover in the adult human heart emerged as early as 1960, although what might constitute the most direct evidence was provided recently in 2009 by Bergman and colleagues.¹¹⁸ Taking advantage of the rise in atmospheric ¹⁴C from Cold War-era nuclear bomb testing that ended in 1963, they approximated that cardiomyocytes renew at 0.45% to 1% per year, gradually declining as one ages.¹¹⁸ Although the actual rate of turnover remains unclear, this evidence firmly established some capacity for myocyte turnover in the heart; however, many fundamental questions persist regarding the heart's ability to self-renew.^{98,119} The source of this capacity was potentially answered by Beltrami and colleagues¹²⁰ in 2003 who identified a niche of stemlike cells existing within the heart of mammals. These putative "cardiac stem cells" were negative for hematopoietic cell lineage markers and positive for stem cell marker c-kit, and they were clonogenic, could self-renew, and were multipotent.¹²⁰ They were capable of differentiating into cardiomyocytes, smooth muscle cells, and endothelial cells.¹²⁰ In addition, when injected into the ischemic rat heart, these cells or their clonal progeny were shown to develop blood carrying vessels and myocytes with features characteristic of younger cells.¹²⁰ Given these properties, the putative "cardiac stem cell" (CSC) may represent the best candidate cell type for cardiac cell therapy.

Since the results released by Beltrami and colleagues, CSC contribution to postnatal cardiomyogenesis has gained support.^{121,122} However, these reports conflict with the firmly established evidence that cardiomyocyte renewal in animals that display considerable cardiac

regenerative potential (e.g., amphibians, zebrafish) occurs via the proliferation of preexisting myocytes and not from the influence of stem cells.⁹⁸ Indeed, contrasting evidence was provided by Senyo and colleagues,¹²³ reporting that either during normal cardiac homeostasis or in response to injury cardiomyocyte renewal in mice occurs by the division of preexisting cardiomyocytes and is not mediated by a stem cell niche. Others, however, provide compelling evidence that c-kit⁺ cardiac stem cells are necessary and sufficient for complete functional and anatomic recovery during diffuse cardiac injury with patent coronary circulation.¹²⁴ These seemingly contradictory observations may be reconciled with the hypothesis that ischemic injury depletes tissue stem cells, possibly including CSCs.¹²³⁻¹²⁶

Despite the uncertainty revolving around the cardiomyogenic potential of CSCs *in situ*, many researchers and clinicians have pursued using this population therapeutically. To date, several methods have been developed to isolate and expand this population *ex vivo* for therapeutic purposes including purified c-kit⁺ cells, cardiosphere-derived cells (CDCs), Sca1⁺ CSCs, side population cells, and islet-1⁺ cells. In this review, we will focus on the CDCs and purified cardiac c-kit⁺ cells (i.e., CSCs), which are the best studied and are the only populations in which there are ongoing clinical trials.^{10,127,128}

C-kit⁺ Cardiac Stem Cells

Cardiac stem cells isolated and purified based on c-kit surface expression are the best characterized in terms of preclinical animal models of cardiovascular disease. Human CSCs injected early after permanent coronary occlusion in immunodeficient mice and immunosuppressed rat hearts were shown to restore some contractile function to the infarcted area of the ventricle, improve ventricular performance, and alleviate some chamber dilation.¹²² In addition, hearts explanted from both animal groups demonstrated chimerism and the coexistence of human and rodent cells together within the infarcted myocardium.¹²² Rota and colleagues¹²⁹ assessed CSC delivery in a model of chronic HF secondary to ischemia where the isolation and injection of CSCs may be more clinically feasible and have shown that injecting CSCs into the border zone of a 20-day-old infarct in rats preserved left ventricular function, successfully replaced a portion of the myocardium, and mitigated some ventricular remodeling.¹²⁹ CSC transdifferentiation into cardiomyocytes has been offered to explain the positive effects of CSC transplantation.¹²⁹ However, others, such as Tang and colleagues,¹³⁰ report that CSC integration with the myocardium could not account completely for the benefits. In their study, GFP⁺ CSCs only occupied 2.6% and 1.1% of the risk and noninfarcted regions, respectively¹³⁰; therefore, a paracrine mechanism likely explains the discrepancy. The beneficial effects of CSC therapy have been replicated in large animal models as well.¹³¹ For example, Bolli and colleagues¹³¹ administered CSCs 3 to 4 months after reperfused MI in swine via the infarcted artery. Swine receiving CSC therapy had significantly greater LV ejection fraction, maximum LV dP/dt, and lower LV end-diastolic pressures at 1 month after treatment.¹³¹ Together, these studies provide proof of

concept that c-kit⁺-selected CSC transplantation may offer functional benefits and may be also capable of promoting some degree of myocardial regeneration during ischemic injury.¹²²

The “Stem Cells Infusion with Patients with Ischemic cardiomyopathy” (SCIPIO) (Clinicaltrials.gov, no. NCT00474461) phase I trial is the only trial at the time of this writing assessing autologous c-kit⁺ lineage-negative CSC therapy for the treatment of an ischemic cardiomyopathy.¹²⁷ Results from the 2-year follow-up of SCIPIO were not available at the time of compiling this chapter, although interim results have been published.^{127,132} SCIPIO is a phase I, open-label, single-center trial assessing CSCs in patients with heart failure secondary to ischemic disease. The open-label design was chosen given that blinding the control cohort would have required cardiac catheterization with placebo infusion.¹²⁷ Patient inclusion criteria included previous myocardial infarction, LVEF less than 40%, and undergoing CABG. CSCs were administered approximately 3 months after CABG being delivered to the proximal coronary artery or graft supplying the infarcted region of the ventricle. Overall, from the interim results, patients that completed the 12-month follow-up had an absolute increase in LVEF of 12.3 points, whereas no improvement was apparent in patients in the control cohort.¹²⁷ The mean LVEF of all patients before treatment was approximately 30%. In addition, the NYHA functional class decreased in all 16 patients receiving CSC treatment from a mean of 2.19 to 1.63 after 4 months and patient responses to the MLHFQ, from 46.44 to 26.69. No changes were reported in the NYHA or the MLHFQ for control patients. CSC collection in the operating room appears not to interfere with standard procedures or outcomes,¹³² and harvest was successful despite the severity of disease, comorbidities, and likely feasible for most patients undergoing CABG. The procedure did not prolong cardiopulmonary bypass time, aortic cross-clamp time, or total surgical time.¹³² In summary, the use of autologous c-kit⁺ CSCs holds much promise, likely deriving from the fact that these cells may represent a cardiac specific stem cell niche responsible for cardiomyocyte homeostasis. Thus far, phase I clinical trial results agree with the preclinical animal models, and the procedure of harvesting and CSC infusion appears to be safe warranting further study in phase II trials.

Cardiosphere-Derived Cells

Cardiosphere-derived cells represent a heterogeneous ex vivo outgrowth cell product derived from cultured cardiac biopsies.¹³³⁻¹³⁵ This subpopulation was first reported by Messina and colleagues¹³⁴ in 2004. The term *cardiosphere* was coined from the observation that ventricular or atrial tissue biopsy subcultures would produce emigrating cells that formed spherical aggregates.¹³⁴ These aggregates contained, among a number of cell types, cardiac progenitors and when injected into the infarcted rat myocardium would produce functional benefits and some histological recovery.¹³⁴ Since its original description, the CDC method has been refined to include endomyocardial biopsy specimens.¹³⁵ Phenotypically, these cells express a wide array of surface antigens, including those

that mark endothelial cells (KDR human; FLK1 and CD31 mouse), embryonic and stem cells (SSEA-1, abcg2, CD34, c-kit, sca-1), and mesenchymal stem cells (CD105, CD90). In rodent models, when injected shortly after experimental infarction, CDCs were associated with improved LVEF and hemodynamic parameters, as well as reduced infarct sizes and increased percentage of viable myocardium.¹³³⁻¹³⁶ In swine, CDCs harvested from endomyocardial biopsy specimens infused 1 month after MI were associated with a reduction in relative infarct sizes compared with control at 8 weeks after treatment.¹³⁷ CDCs were also associated with improved hemodynamic parameters such as higher dP/dt maximum and lower dP/dt minimum, and no instances of infarction related to cell infusion was reported.¹³⁷ However, CDC infusion did not reduce final infarct size, improve LV mass, or improve contractile function of the ventricle.¹³⁷ Allogeneic CDC transplant has also been documented as being safe and relatively non-immunogenic in pre-clinical models.¹³⁶ Transplantation without immunosuppression appears safe and functional results are consistent with previous studies.¹³⁶

The CDC method for isolating CSCs has been sharply criticized with claims that cardiospheres represent primarily a culture of fibroblasts and other cardiac cell contamination,¹³⁸ but this view is not universal as others have shown that adult cardiac stem cells can be grown directly from myocardial biopsies.¹³⁹ The promising preclinical results warranted investigation in a phase I clinical trial. To date, three clinical trials are complete or ongoing studying the use of CDCs for cardiac regeneration; these include “CARDiosphere-Derived aUTologous Stem Cells to Reverse ventricUlar dysfunction” (CADUCEUS) trial (NCT008933602), the “AutoLogous Human CARDiac-Derived Stem Cell to Treat Ischemic cARDiomyopathy” (ALCADIA; NCT00981006), and the “Allogeneic Heart Stem Cells to Achieve Myocardial Regeneration” (ALLSTAR; NCT01458405) trials. The CADUCEUS study involves the use of CDC products from septal endomyocardial biopsy specimens, the ALCADIA trial will be assessing bFGF slow release concomitant with CDC therapy, while ALLSTAR will assess allogeneic CDC transplant. At the time of this writing, both ALLSTAR and ALCADIA are in the process of recruiting patients, and results were only available for the CADUCEUS trial.¹²⁸ The CADUCEUS trial assessed CDC therapy for patients with recent myocardial infarction (≤ 4 weeks) and significant left ventricular dysfunction (LVEF $\geq 25\%$, $\leq 45\%$). Patients were randomly assigned to a treatment group, and those receiving CDC therapy were administered the product (≤ 90 days after myocardial infarction) via over-the-wire angioplasty catheter in the infarct-related artery.¹²⁸ The primary endpoint was safety 6 months after infusion, including ventricular tachycardia, fibrillation, sudden unexpected death, and MI after infusion.¹²⁸ Efficacy was assessed in terms of the NYHA class, MLHFQ, 6-min walk test, and MRI. CDC therapy did not produce complications within 24 hours of infusion. Overall, CDC therapy seems safe, with 24% of patients in the CDC group having experienced serious adverse events compared to 13% in the placebo, but conclusions are difficult to draw given the

low number of patients included in the study. There were no differences reported in NYHA, or MLHFQ scores. Patients receiving CDC at 1 year increased walked distance compared with controls. No differences in LVEF were reported; however, MRI non-gadolinium-enhanced tissue in CDC patients showed reduced scar mass, increased viable heart mass, regional contractility, and regional systolic wall thickening. There were no benefits in terms of end-diastolic volume, end-systolic volume, and LVEF by 6 months. The lack of benefit in terms of global cardiac function, particularly LVEF, is consistent with the large-animal model published by Johnston and colleagues.¹³⁷

Overall, CDCs are a heterogeneous population of cells that can be derived from several available subculture methods of atrial, ventricular, or endomyocardial biopsy specimens. Some controversy exists as to the cardiomyogenic potential of this product, but there appears to be more proponents than critics. Unfortunately, the clinical effects of CDC therapy are somewhat mixed. Results from the CADUCEUS study did not confirm meaningful effects on cardiac function or clinical status in patients treated with CDCs. Overall, CDCs represent an alternative method to the lineage-negative c-kit⁺-purified CSC, although based on available evidence further assessment of clinical outcomes is required.

Combination Products

The clinical experience with most of the cell populations studied thus far have unarguably not met with expectations motivated by preceding preclinical results. A number of laboratories have investigated combining different cell types in the effort of taking advantage of complementary modes of action and possible synergistic effects. Some examples follow.

Early and late EPCs appear to promote neovascularization through separate modes of actions. Early-EPCs seem to be proangiogenic on account of a paracrine mechanism, whereas late EPCs tend to integrate directly within the microvasculature.⁵⁸ Given these separate yet complementary mechanisms of action, Yoon and colleagues¹⁴⁰ demonstrated that infusing a combination of early and late EPCs promotes a synergistic effect on neovascularization. Similarly, Latham and colleagues¹⁴¹ cotransplanted CDCs with early EPCs 1 week post-MI in mice. In vitro both cell types promoted equivalent vascular networks, whereas the cell types had distinct cytokine profiles. Each offered similar functional benefits when transplanted alone, though when transplanted together offered a complementary effect on function superior to the benefits of either cell type individually.¹⁴¹ In swine with reperfused MI, Williams and colleagues¹⁴² reported that combined transplantation of MSCs and CSCs reduced infarct sizes twofold greater in combination than either cell alone, and the combination therapy restored cardiac functional parameters, such as EF, to baseline. These studies represent a growing body of evidence that begs the question as to whether the future of cell therapy will need to rely on novel strategies, such as multiple cell sources, to achieve the desired clinical outcome.¹⁴⁰

POTENTIAL MECHANISMS OF ACTION FOR CELL-BASED REGENERATIVE THERAPIES

Our experience so far with cell-based regenerative therapies is that they are safe, feasible, and potentially beneficial for a number of clinical settings, including AMI, chronic ischemic cardiomyopathy, refractory angina, and heart failure. However, a major gap that persists is understanding the mechanisms underpinning their benefits. The following sections will describe our current understanding of the mechanisms of action of cell based therapeutics in cardiac regenerative medicine. A schematic representation of the major proposed mechanisms of action of transplanted cells is shown in [Figure 101-4](#).

Transdifferentiation and Cell Fusion of Transplanted Cells

The initial hope with cell-based therapies was that it would provide a means of regenerating previously lost myocardium through transdifferentiation to cardiomyocytes. It also may appear to be the most obvious justification to explain the salutary effects of cell therapies; however, with the evidence that is available to date, it does not appear to be the major mechanism, if providing any contribution at all. For example, the transdifferentiation of bone marrow cells, including CD34⁺ selected cells,^{73,75,76,160} has equally as many critics^{16,17} as there are supporters.^{49,143} Instead, the concept of BMC cell-fusion with resident cardiomyocytes has been proposed, but again this has also been contested.^{144,145} Initially, MSCs appeared to participate in cardiomyogenic phenomena as well, although now their benefits are believed to be derived primarily from their robust secretome.* CSCs have been reported to produce all major cardiac lineages,^{120,126,129,130,149} yet some reports deem this process insufficient to account for the improvement in cardiac function.¹³⁰ The evidence supporting the cardiomyogenic potential of CDCs is somewhat less nebulous, reported as either quite minimal¹⁵⁰ or nonexistent altogether.¹³⁶

It is possible that transplanted cell therapies have been able to regenerate cardiomyocytes within damaged myocardium. How much is occurring and the overall contribution to the functional effects are the questions that remain. Most reports to date agree that if any cardiomyogenesis occurs, it is certainly disproportionate with the magnitude of the benefits. Instead, other mechanisms are more likely.

Neovascularization from Transplanted Cells

Many of the cell types discussed have been demonstrated to offer some capacity to contribute to the formation of new blood vessels within the myocardium including BMCs, CSCs, MSCs, and CD34⁺ cells ([Fig. 101-5](#)).^{15,73,149,151} Neovascularization may prove beneficial in

*References 77, 78, 80, 82, 84, 146-148.

FIGURE 101-4 ■ Proposed mechanisms of action for transplanted stem cells. Transplanted stem cells were originally thought to participate in cardiac repair via direct transdifferentiation (*right side, thin arrow*). We now understand the contribution of cell fusion and transdifferentiation of stem cells to cardiomyocytes and neovascularization to occur very minimally, if at all (denoted by *thin arrow*). Instead the predominant hypothesis is that transplanted stem cells influence the behavior and survival of resident cells through paracrine effects (*left side, thick arrow*). Transplanted stem cells can release soluble growth factors, angiogenic cytokines, and microRNA that together serve to promote neovascularization, activate resident cardiac stem cells, favorably alter extracellular matrix (ECM) remodeling, confer cardioprotection, inhibit cardiac hypertrophy, and modulate inflammation. Intervening on these processes may ameliorate this emerging cardiac therapeutic modality.

FIGURE 101-5 ■ Transplanted cell contribution to neovascularization. Transplanted endothelial progenitor cells (**A**) and mesenchymal stem cells (**B**) contributing to the formation of capillaries within muscle fibers. Arrows indicate positive α -smooth muscle acting staining in arterioles. Scale bar = 150 μ m.

settings where the region of interest may constitute ischemic, but viable, myocardium. However, the benefits of increasing blood vessel density are less clear in many clinical scenarios. For example, in a scar from an old MI or during acute reperfused MI, it is hard to imagine how increased vascular density would be advantageous. Perhaps settings such as refractory angina or chronic ischemic cardiomyopathy are examples of when benefits may be potentially derived from increased vessel density, but this is not the case with all clinical scenarios.

The Paracrine Hypothesis

Paracrine effects is the reigning hypothesis to explain the benefits associated with transplanted cells. *Paracrine* refers to the capacity of transplanted cells to release signal and growth factors (cytokines, chemokines, exosomes, microparticles, and microRNAs) into the extracellular milieu affecting the behavior and survival of neighboring cells.^{146,151,152} Examples of the reparative processes associated with paracrine effects include neovascularization,

cardioprotection, modulating inflammation, inhibiting remodeling, antihypertrophic responses, and activation of resident cardiac stem cells.

Neovascularization

The ability to promote neovascularization for most cell types is a result of the release of various chemokines (SDF-1a),^{153,154} proteins (e.g., VEGF, bFGF, IGF-1),^{155,156} and microRNAs, potentially through exosomes.^{66,157,158} The cardioprotective benefits associated with c-kit⁺ cells from the bone marrow after MI is a result of the modulation of the angiogenic cytokine milieu.¹⁵⁹ Reestablishing blood supply in some situations could salvage ischemic myocardium in diseases such as chronic ischemic cardiomyopathy, though as discussed, this mechanism likely does not account for benefits in patients without residual or persistent ischemia.

Cardioprotective

Paracrine-mediated cardiomyocyte salvage in an ischemic environment is an effect of transplanted cells.^{146,151} For example, the functional benefits associated with MSCs appear to occur despite the lack of any evidence of their long-term engraftment within the myocardium.⁸⁴ A number of reports indicate that some of these benefits stem from antiapoptotic effects of secreted factors on cardiomyocytes and endothelial cells.^{77,84,160} Cytoprotective paracrine effects seem to underpin a number of other candidates of cell therapy, including IPSC derived endothelial cells,¹¹² BMCs,^{60,158} EPCs,¹⁵² and cardiac-derived stem cells.¹⁵⁰ The release of IGF-1 and subsequent inhibition of miR-34a processing from transplanted BMCs was recently shown to contribute to the paracrine protective effect of this cell type.¹⁵⁸

Modulation of Inflammation

Chronic, unabridged inflammation is a major determinant of the severity of disease in ischemic cardiomyopathies.¹⁶¹ Injected cells, such as MSCs, can act as guardians of inflammation attenuating the local inflammatory response by releasing signaling molecules within the environment.⁸⁰ Transplanted MSCs into ischemic zones have been shown to decrease proinflammatory cytokines, such as TNF- α , IL-1 α , and IL-6.¹⁴⁶ This may be, in part, mediated by the secretion of anti-inflammatory protein TSG-6.¹⁶² Intravenously infused MSCs after MI in mice were shown to embolize to the lungs, secrete TSG-6, and improve cardiac function and reduce infarct sizes.¹⁶²

Extracellular Matrix Remodeling

The effect of the extracellular matrix (ECM) on proper functioning of the heart cannot be overstated. The stability and dynamic equilibrium of the ECM with cardiomyocytes ensures proper alignment and prevents overstretching of myocytes.¹⁶³ It is also equally important in secondary roles, such as ensuring proper functional and electrical behavior of the myocardium and vasomotor reactivity of coronary microvasculature.¹⁶³ In pathologic

scenarios, such as myocardial infarction, impaired remodeling of the ECM plays a substantial role in LV dilation and dysfunction, and morbidity and mortality.¹⁶⁴ At the molecular level, an imbalance in matrix metalloproteinases (MMPs) and tissue-inhibitors of MMPs (TIMPs) production favors this impaired remodeling.¹⁶⁴ Paracrine factors released by transplanted cells may serve favorably to influence the outcome of ECM remodeling post-injury. For example, MSCs have been shown to decrease postinfarct fibrosis.¹⁴⁶ In a rat model of dilated cardiomyopathy, transplanted MSCs decreased MMP-2 and MMP-9 expression, leading to reduced fibrosis and improved function.¹⁶⁵ Rota and colleagues¹²⁹ demonstrated that transplanted CSCs increased MMP-2, MMP-9, and MMP-14, while decreasing TIMP-4 levels in a model of HF secondary to MI in rats.

Inhibition of Hypertrophy

Stem cells therapies have been shown to reduce the hypertrophic response of cardiomyocytes in models of ischemic heart failure.^{129,130} It is uncertain, however, whether this is secondary to reduced cardiac stress and improved function or whether it constitutes a principal, paracrine function of transplanted cells.

Activation of Resident Cardiac Stem Cells

Endogenous cardiac stem cells are considered to play an important role in cardiac homeostasis, particularly in the turnover of resident cardiomyocytes.¹²⁴ Some cell types have been shown to activate endogenous CSCs. For example, Loffredo and colleagues⁵¹ demonstrated that c-kit⁺ bone marrow cell stimulation of endogenous CSC cardiogenic activity was a critical mechanism of the therapy. The authors also reported that this function was limited to c-kit⁺ BMCs and not MSCs, although others have shown similar results with MSC therapy.^{82,148} The contribution of activated endogenous CSCs also has been shown to be significant with CSC-based cell therapy.¹³⁰

CURRENT CHALLENGES AND FUTURE DIRECTIONS FOR CARDIAC REGENERATIVE MEDICINE

As we move forward in translating new cell therapies into the clinic, we must approach the next steps with careful optimism as many challenges and obstacles remain.¹⁶⁶ Indeed, recent successes in the laboratory and the convergence of different fields, such as tissue engineering, provides exciting opportunities as we work toward finally achieving our goal of cellular cardiomyoplasty. The early experience with stem cell therapy was largely positive, particularly with BMCs. However, since these initial pilot trials ensuing results have contradicted early reports and recent, larger trials have not been able to resolve the controversy reporting positive,³¹ somewhat positive,⁷⁴ mixed,³⁵ and negative findings.^{167,168} Other cell types have been equally controversial, and providing an explanation is difficult. Likely the answer is multifactorial and cumulative. The inconsistency in reported outcomes for stem

cells may arise from clinical factors such as patient clinical characteristics and definitions of efficacy, or other elements such as the limited engraftment or survival of transplanted cells and their dysfunction.¹⁶⁶

Patient Clinical Characteristics

Cumulative evidence from BMC therapy supports modest improvements in clinical parameters such as left ventricular function. These benefits appear to be comparable to current interventions such as primary PCI, mechanical revascularization, or pharmacologic therapy. Unlike BMC therapy, conventional treatments have proven survival outcomes and a well-established routine in clinical practice.¹⁶⁹ Thus, cell therapy may prove unnecessary and equally lack any benefit for some or most patients. In many of the discussed trials, patient cohorts comprised a relatively healthy patient population with reperfused AMI and minor dysfunction ($\geq 50\%$ LVEF) also treated with contemporary medical therapy. Given the comparatively minor dysfunction in these patients, it is possible that they were not those who could derive the most benefit from stem cell therapy. Interestingly, in trials in which patients were stratified based on clinical characteristics (e.g., severe cardiac dysfunction), the greatest benefits appeared to occur in the sickest patients (low baseline EF).^{26,31,74} The implications for future investigations and cardiac therapy altogether are that potentially cell therapy is maximized in those who can possibly derive the greatest benefit—the very ill.

Measures of Efficacy

The prevailing surrogate marker to assess benefits derived from cell therapy has been cardiac left ventricular function, specifically LVEF. Indeed, it is possible that improvements in EF might not be best suited for our definition of efficacy, as EF can be dependent on neurohumoral influences, ventricular geometry, or load. Other metrics of improvement, such as changes in geometry, scar size, perfusion, and viable myocardium measured with modern imaging modalities (e.g., cardiac MRI or PET), may be more appropriate along with other clinically relevant metrics, such as mortality.

Transplanted Cell Dysfunction and Ex Vivo Cell Priming

Clinical trial results have obviously not been as compelling as the preclinical evidence that originally inspired their use in patients. One possible explanation is that, often, many clinical parameters are not recapitulated in animal models. For example, in contrast to preclinical rodent studies in which both donors and recipients are often healthy, young animals, patients are far from healthy and often suffer from other comorbidities. Thus, donor cells from preclinical animal studies are likely poor approximations of the clinical autologous products. For example, BMCs have been shown to be impaired functionally in the setting of diabetes, previous MI, and heart failure, and because of on-pump coronary bypass.^{56,170,171} CSC function and survival, equally, appear to be impaired

by diabetes.¹⁷² In mice, recent MI impairs donor BMC therapeutic efficacy because of a high inflammatory state in the donor bone marrow.¹⁷⁰ As the proper functioning of autologous cells appears to depend on individual patient characteristics, several investigators have sought to use novel methods, such as priming cells *ex vivo*, to circumvent these potential limitations.¹⁹ For example, our group developed a collagen I-based biomaterial matrix as a substrate to improve the potency of cultured early EPCs.¹⁷³ This culture method resulted in a higher proportion of CD34⁺ and CD133⁺ EPC progenitors and improved their capacity to direct *de novo* neovascularization compared with the traditional method of culture on fibronectin.¹⁷³ Other examples include Noiseux and colleagues,⁸³ who showed that over-expressing Akt in MSCs improves transplanted cell retention and engraftment. The Akt-MSCs were superior at reducing infarct sizes and improving cardiac function.⁸³ Overexpressing endothelial nitric oxide synthase (eNOS) in transplanted cells is an example of priming cells that is currently under clinical investigation.^{19,174} Reduced eNOS expression and nitric oxide (NO) production have been implicated in both endothelial dysfunction¹⁷⁵ and in impaired progenitor cell function.^{174,176} Pretreating BMCs *ex vivo* with an eNOS enhancer was demonstrated to rescue this dysfunction and improve their therapeutic efficacy in preclinical studies.¹⁷⁷ The Enhanced Angiogenic Cell Therapy in Acute Myocardial Infarction (ENACT-AMI; NCT00936819)¹⁷⁴ trial will be the first of its kind to assess transgenic, enhanced stem cells. Autologous early EPCs will be transfected with human eNOS to improve their angiogenic potency and cells will be delivered in patients with significant LV dysfunction after MI.¹⁷⁴ The trial is actively recruiting patients, and the first patient was treated in September 2013 in Ottawa, Canada.

Autologous versus Allogeneic Cells

The vast majority of clinical trials for cell therapy have investigated autologous products and depending on individual patient clinical features autologous cells may be suboptimal.¹⁶⁶ This source of cell therapy is obviously attractive as it circumvents challenges involved in allograft surgeries such as immunologic graft rejection.¹⁶⁶ On the other hand, allogeneic products could be advantageous as “off-the-shelf” products obviating the surgical pragmatic concerns of procuring and culturing patient-derived cells, particularly if they are to be infused soon after AMI. They could be highly standardized and produced in large numbers.¹⁶⁶ In turn, this could ensure the cost-efficient, timely and safe access to a cell therapy product. Immune rejection is an obvious concern, as is the potential for eventual immune tolerance. MSCs may be promising candidates as evidenced by the POSEIDON and Prochymal trials^{89,90} given their purported immune-privilege.⁸⁰

Cell Engraftment and Biomaterials

Unfortunately, whether cells have been autologous or allogeneic therapies retention and engraftment continues impede optimal performance.¹⁷⁸ Regardless of delivery method, cell type or method used to assess cell retention

FIGURE 101-6 ■ Stem cell therapy transplanted with collagen-based biomaterial matrix can synergize to improve cell engraftment and functional benefits. **A**, Small animal positron emission tomographic images at 150 minutes after endothelial progenitor cell (EPC) injection into the ischemic hind limb muscle. Images of transplanted ¹⁸F-FDG-labeled EPCs delivered with the matrix showed significantly higher retention compared with the cells injected alone. **B**, C-kit⁺ cell recruitment is greater in EPCs + matrix-treated MI hearts at 1 and 3 weeks after treatment. PBS, Phosphate-buffered saline.

and survival, generally, only a small fraction of transplanted cells are retained within the myocardium over the short term.¹⁷⁸ Over the long term, the loss of transplanted cells is cumulative as attrition worsens.¹⁷⁸ Our group and others have investigated merging principles from tissue engineering and cell therapy to improve the engraftment, retention, and survival of transplanted cells.^{179,180} Suuronen and colleagues¹⁸⁰ assessed the efficacy of CD133⁺ EPCs delivered in a collagen I-based injectable hydrogel matrix in rat ischemic hindlimb. Transplanting cells within the biomaterial improved their retention greater than twofold (Fig. 101-6A), and rats receiving the combined therapy had greater arteriole and capillary densities in the ischemic hind limb compared with cells delivered alone.^{180,181} More recently, we demonstrated that delivering early EPCs with the hydrogel matrix improved transplanted cell engraftment and the recruitment of endogenous c-kit⁺ cells (see Fig. 101-6B), and synergized to improve viability, perfusion, and function of infarcted myocardium.¹⁸² Other investigators from our institute demonstrated that CSCs encapsulated within matrix-enriched capsules delivered in a murine MI model improved the long-term retention of cells and also resulted in greater functional recovery and reduced infarct sizes.¹⁷⁹

In Situ Cell Therapy

The mainstay of current cell therapies has been a workflow of cells that (1) are procured from a donor

(autologous or allogeneic), (2) are or are not further purified and/or primed, and (3) are delivered either via direct injection or intravenous or intracoronary infusion. This process may still hold some clinical potential, but it is costly, labor intensive, and relatively inefficient at promoting cardiac regeneration, if at all. Emerging advances in cell reprogramming may offer new opportunities, including in situ cell therapy. Several authors demonstrated that fibroblasts migrating to and populating the infarcted region of the heart may be reprogrammed into cardiomyocyte-like cells or inducible cardiomyocyte-like cells using a technique similar to the one required to produce iPSCs.^{98,183,184} The efficiency of this procedure is low, with only 7% to 15% of cardiac fibroblasts converted to cardiomyocyte-like cells, but resulted in profound reductions in scar size and improvements in cardiac function.^{183,184} Optimizing the efficacy and safety of this process are obvious requirements for translating them into the clinic; nevertheless, it provides an exciting alternative to the currently accepted paradigm of ex vivo cell therapy. Other groups have investigated similar methods at promoting cardiac regeneration in situ.¹⁸⁵ Eulalio and colleagues¹⁸⁵ demonstrated that administration of select microRNAs markedly stimulated cardiomyocyte proliferation in the border zone and resulted in almost complete anatomic and functional recovery. MicroRNAs may constitute another novel method for in situ cell therapy.

SUMMARY

We are currently in an exciting phase of cardiac cell therapy. Although early forays have not exactly measured up to our initial expectations, we are definitely wiser for it. As we move forward in trying to find the optimal therapy to regenerate the injured heart several pressing issues require addressing. First, we need to return to the laboratory to further understand regenerative mechanisms and how they may be mediated up to improve the efficiency of current and future therapies. Second, an iterative and systematic process of identifying the optimal cell type, dose, and delivery method is required and needs to be substantiated by well-designed, large-multicenter trials for each clinical entity. Moreover, these effects need to be followed up with sufficient power to prove benefits as well as safety. It is possible that BMCs will likely be forgotten as alternatives emerge with proven abilities to repair injured myocardium. Further still, ex vivo cell therapy may die out and lose favor with clinicians and investigators as tissue engineering or in situ methods evolve. It is difficult to predict which cell type or technology might ultimately prevail in our pursuit of a cardiac regenerative therapy, though given that the need for such a therapy will not likely subside anytime soon, the pursuit will continue passionately until we can finally mend a broken heart.

SURGERY FOR PULMONARY EMBOLISM

Patricia A. Thistlethwaite • Michael Madani • Stuart W. Jamieson

CHAPTER OUTLINE

ACUTE PULMONARY THROMBOEMBOLIC DISEASE

Clinical Points
Prophylaxis
Supportive and Thrombolytic Therapy
Percutaneous Treatments
Acute Pulmonary Embolectomy
Extracorporeal Life Support
Results of Surgical Embolectomy for Acute Pulmonary Embolism

CHRONIC PULMONARY THROMBOEMBOLIC DISEASE

Incidence and Natural History
Clinical Manifestations

Diagnostic Evaluation of Chronic Thromboembolic Pulmonary Hypertension
Surgical Selection
Guiding Principles of the Operation
Pulmonary Endarterectomy: Surgical Technique
Thromboembolic Disease Classification and Prediction of Surgical Outcome
Results of Pulmonary Endarterectomy Surgery
Alternative Therapies for Chronic Thromboembolic Pulmonary Hypertension

SUMMARY

Pulmonary thromboembolism is a significant cause of morbidity and mortality in the United States and worldwide. The estimated incidence of acute pulmonary embolism is approximately 63 per 100,000 patients in the United States, based on clinical and radiographic data.¹ Acute pulmonary embolism is the cause of approximately 235,000 deaths per year based on autopsy data. Acute pulmonary embolism occurs half as often as acute myocardial infarction and is three times as common as cerebrovascular accident. It is the third most common cause of death (after heart disease and cancer).² Estimates of the incidence of acute pulmonary embolism, however, are generally thought to be low, because in 70% to 80% of patients in whom the primary cause of death was pulmonary embolism, the diagnosis was unsuspected premortem.^{3,4}

Of patients who survive an acute pulmonary embolic event, approximately 3.8% will go on to develop chronic pulmonary hypertension (PH).⁵ Once PH develops, the prognosis is poor, and this prognosis is worsened in the absence of intracardiac shunt. Patients with PH caused by pulmonary emboli fall into a higher risk category than those with Eisenmenger syndrome, and they encounter a higher mortality rate. In fact, once the mean pulmonary pressure in patients with thromboembolic disease exceeds 50 mm Hg, the 3-year mortality rate approaches 90%.⁶ Despite an improved understanding of pathogenesis, diagnosis, and management, pulmonary emboli and their long-term sequelae remain frequent and often fatal disorders.

Pulmonary embolism was first described by Laennec in 1819.⁷ It was he who related the condition to deep

venous thrombosis, and Virchow⁸ later associated the three factors predisposing to venous thrombosis as stasis, hypercoagulability, and vessel wall injury. Virchow distinguished two types of thrombus in the pulmonary arteries of such patients: the embolus that arose as thrombus in a systemic vein and the thrombus that occurred in situ within the pulmonary arteries distal to the occluding embolus as a result of the stagnant blood flow in that segment. To prove that pulmonary emboli arose from the peripheral venous circulation, Virchow inserted pieces of rubber or venous thrombi recovered from humans at autopsy into the jugular or femoral veins of dogs. When the animals were sacrificed, the foreign embolic material was found in the pulmonary arteries. Although pulmonary embolism can be caused by tumors, septic emboli, and foreign bodies, the overwhelming occurrence of pulmonary embolism is due to venous thromboembolism.⁹

ACUTE PULMONARY THROMBOEMBOLIC DISEASE

Clinical Points

The majority of pulmonary thromboembolic episodes are silent, and it is not until the amount of embolic material is substantial that the patient becomes symptomatic. After an acute, major thromboembolic episode, approximately 15% to 20% of patients die within 48 hours.¹⁰ Most of the remaining patients resolve the emboli substantially by a variety of mechanisms. Therefore, it is in

the subgroup of patients who have a sudden fatal outcome ($\approx 100,000$ annually) that invasive therapy for acute pulmonary embolism might be considered.

Although the role of surgical therapy for the PH resulting from chronic pulmonary emboli is now well established, the appropriate treatment for acute pulmonary embolism remains unclear. There are several reasons for this. Many patients die of massive pulmonary embolism in the terminal phases of another illness, which would make aggressive therapy inappropriate. For patients in whom invasive therapy is potentially indicated, there is substantial difficulty in defining which patients will respond to anticoagulation therapy for an acute massive pulmonary embolism in the limited amount of time available for diagnosis and treatment before death occurs.

The hemodynamic response to a large, sudden pulmonary embolus relates to a variety of factors, most notably the size of the embolus, the degree of obstruction that it produced in the pulmonary vascular bed, and the underlying function of the lung that remains perfused. The degree of vascular obstruction is related to the number of segmental arteries that are occluded and to prior pulmonary vascular capacitance. Thus, the hemodynamic consequences of acute pulmonary embolism are also a reflection of factors, such as the age of the patient and any possible previous thromboembolic events. The pre-existing status of the right ventricle that governs the forward flow of blood is also significant in determining the hemodynamic response to pulmonary embolism. Right ventricular function is affected by factors such as the degree of right ventricular hypertrophy or dilation, tricuspid valve regurgitation, and the presence of coronary artery disease.

In addition to the mechanical factor of pulmonary artery obstruction, there are reflex and hormonal factors that can increase pulmonary vascular resistance (PVR) at the time of acute pulmonary embolism. Humoral factors, specifically serotonin, adenosine diphosphate, platelet-derived growth factor, and thromboxane, are released from platelets attached to the thrombi,^{11,12} whereas platelet-activating factor and leukotrienes are secreted by neutrophils.¹³ Anoxia and tissue ischemia downstream from emboli inhibit endothelium-derived relaxing factor production and enhance release of superoxide anions by activated neutrophils.¹⁴ The combination of these humoral effects contributes to enhanced pulmonary vasoconstriction. Thus, some patients with a relatively small embolus may have an exaggerated response to the degree of pulmonary vascular obstruction.

In patients without preexisting cardiac or pulmonary disease, an obstruction of less than 20% of the pulmonary vascular bed results in minimal hemodynamic consequences. It is only when the acute pulmonary obstruction exceeds 50% to 60% of the pulmonary vascular bed that cardiac and pulmonary compensatory mechanisms are overcome and cardiac output begins to fall.¹⁵ Right ventricular failure occurs, which is accompanied by systemic hypotension as the amount of blood reaching the left ventricle decreases. The dilated right ventricle causes a shift of the ventricular septum to the left, further compromising left ventricular filling. Although patients with

chronic pulmonary artery obstruction can have high pulmonary artery pressure levels that reflect the degree of obstruction, in acute pulmonary embolism the previously normal right ventricle cannot generate these pressures. Therefore, in acute massive pulmonary embolism, pulmonary artery pressures may be normal, and a pulmonary artery systolic pressure of 30–40 mm Hg may represent severe PH.

Acute pulmonary embolism usually presents suddenly. Symptoms and signs vary with the extent of blockage, the magnitude of humoral response, and the preembolus reserve of the cardiac and pulmonary systems of the patient.¹⁶ The clinical diagnosis is often missed or falsely made. Most pulmonary emboli occur without sufficient clinical findings to suggest the diagnosis, and in an autopsy series of proven emboli, only 16% to 38% of patients received a diagnosis while still alive.¹⁷ The acute disease is conveniently stratified into low-risk, submassive, or massive embolism on the basis of hemodynamic stability, arterial blood gases, and lung scan or angiographic assessment of the percentage of blocked pulmonary arteries.^{18,19}

For patients with minor pulmonary embolism, physical examination may reveal tachycardia, rales, low-grade fever, and sometimes a pleural rub. Heart sounds and systemic blood pressure are often normal; sometimes the pulmonary second sound is increased. Less than one third of patients with acute pulmonary embolism have concurrent evidence of clinical deep venous thrombosis.¹⁷ Room air arterial blood gases indicate a PaO_2 between 65 and 80 torr and a normal PaCO_2 of approximately 35 torr.²⁰ Pulmonary angiograms typically show less than 30% occlusion of the pulmonary arterial vasculature. Recent studies suggest that normotensive patients who have normal biomarker levels (Brain Natriuretic peptide [BNP], N-terminal pro-BNP, Troponin I, Troponin T) and have no RV dysfunction on echocardiographic imaging have short-term mortality rates approaching 1%.^{21,22,23}

Submassive pulmonary embolism is defined as an acute pulmonary embolism without systemic hypotension (systolic blood pressure > 90 mm Hg) but with either right ventricular dysfunction or myocardial necrosis.¹⁹ This form of embolism is associated with dyspnea, tachypnea, dull chest pain, and some degree of cardiovascular changes manifested by tachycardia, mild to moderate hypotension, and elevation of central venous pressure.²⁰ Some patients may have syncope rather than dyspnea or chest pain. In contrast to massive pulmonary embolism, patients with submassive embolism (at least two lobar pulmonary arteries obstructed) are usually hemodynamically stable and have adequate cardiac output.²⁴ Room air blood gases reveal moderate hypoxia, with a PaO_2 between 50 and 60 torr, and mild hypocarbia, with a PaCO_2 no more than 30 torr.²⁰ Echocardiograms may show right ventricular dilation. Pulmonary angiograms indicate that 30% to 50% of the pulmonary vasculature is blocked; however, in patients with preexisting cardiopulmonary disorders, a lesser degree of vascular obstruction may produce similar symptoms.

Massive pulmonary embolism is life threatening and is defined as a pulmonary embolism that causes

hemodynamic instability, requiring inotropic support.²⁴ It is usually associated with occlusion of more than 50% of the pulmonary vasculature, but it can occur with much smaller occlusions, particularly in patients with preexisting cardiac or pulmonary disease. The diagnosis is clinical, not anatomical. Patients develop acute dyspnea, tachypnea, tachycardia, and diaphoresis and may lose consciousness. Both hypotension and low cardiac output (<1.8 L/min/m²) are present. Cardiac arrest can occur. Neck veins are distended, central venous pressure is elevated, and a right ventricular impulse may be present. Room air blood gases show severe hypoxia ($\text{PaO}_2 < 50$ torr), hypocarbia ($\text{PaCO}_2 < 30$ torr), and acidosis.²⁰ Urine output falls, and peripheral pulses and perfusion are poor.

The clinical diagnosis of submassive or massive pulmonary embolism is unreliable and is incorrect in 70% to 80% of patients who have subsequent angiography.²⁵ The differentiation between submassive or massive pulmonary embolism and acute myocardial infarction, aortic dissection, septic shock, and other catastrophic states can be difficult and costly in time. Although plain chest radiography, electrocardiogram, and insertion of a bedside Swan-Ganz catheter may add confirmatory information, they will not necessarily prove the diagnosis. Routine laboratory test results are usually normal.

The most common electrocardiographic abnormalities of acute pulmonary embolism are tachycardia and nonspecific ST and T wave changes. The major value of the electrocardiogram is the exclusion of a myocardial infarction. A minority of patients with massive embolism may show evidence of cor pulmonale, right axis deviation, or right bundle branch block.¹⁷ Chest radiography may show oligemia (Westermarck sign) or linear atelectasis (Fleischner lines), both of which are nonspecific findings. Ventilation-perfusion (V/Q) scans can provide confirmatory evidence, but these studies can be unreliable because pneumonia, atelectasis, previous pulmonary emboli, and other conditions can cause a mismatch in ventilation and perfusion that mimics positive results.²⁶

In general, negative V/Q scans exclude the diagnosis of clinically significant pulmonary embolism. V/Q scans are usually interpreted as high, intermediate, or low probability of pulmonary embolism to emphasize the lack of specificity but high sensitivity of the test.²⁷ Magnetic resonance angiography is an excellent noninvasive method for the diagnosis of pulmonary emboli, and it provides specific information regarding flow within the pulmonary vasculature.²⁸ Unfortunately, this method is expensive, time consuming, and not widely available. Like catheter-based pulmonary angiography, it is generally not suitable for hemodynamically unstable patients. Transthoracic echocardiography or transesophageal echocardiography with color flow Doppler mapping can provide reliable information about the presence or absence of major thrombi obstructing the main pulmonary artery; however, these techniques are usually inadequate for visualization of the lobar vessels, where the embolic material is often localized. More than 80% of patients with clinically significant pulmonary embolism have abnormalities of right ventricular volume or contractility, often associated with acute tricuspid regurgitation.²⁹ In a subset of patients, abnormal flow patterns can

be discerned in major pulmonary arteries during transesophageal echocardiography.³⁰

Prophylaxis

Although prophylactic measures should be considered and used for all patients undergoing major surgery or who have prolonged immobility, certain other patients also fall into a potentially high-risk group for pulmonary embolism. These patients include those with previous embolism, malignancy, cardiac failure, obesity, or advanced age.³¹ The prevalence of deep venous thrombosis of the thigh or pelvis, its strong association with pulmonary embolism, and the identification of the associated risk factors listed earlier provide the basis and rationale for prophylactic anticoagulation for the prevention of acute pulmonary embolism. Simple measures such as compression stockings probably should be prescribed more often and should be used in most nonambulating patients in the hospital. Intermittent pneumatic compression devices are more cumbersome, but also effective. These compression devices are available for the calf or the whole leg. They can provide a range of compression pressures, inflation and deflation duration, and sequential or nonsequential inflation, although a clear difference between these variations has not been demonstrated. Both compression stockings with a compression pressure of 30 to 40 mm Hg at the ankle and pneumatic compression devices reduce the incidence of deep venous thrombosis after general surgery to approximately 40% of control patients.³² Multiple studies have shown that low-dose subcutaneous heparin or low-molecular-weight heparin given once a day reduces the incidence of deep venous thrombosis^{33,34} with a concomitant reduction in the incidence of pulmonary embolism. This reduction in thrombosis has not been associated with an excessive risk of bleeding.³³ Recent studies suggest that of patients who have deep venous thrombosis diagnosed in the hospital without pulmonary embolism, the probability of clinically diagnosed pulmonary embolism within the next 12 months is 1.7%.³⁵ If pulmonary embolism occurs, the probability of recurrent pulmonary embolism is 6%.³⁵

Supportive and Thrombolytic Therapy

The majority of patients who die of pulmonary embolism do so within 2 hours of the initial acute event, before the diagnosis can be firmly established and before effective therapy can be instituted. Once the diagnosis is made, however, treatment will be either medical (supportive and thrombolytic therapy) or surgical (Fig. 102-1).

Oxygen should be administered to alleviate hypoxic pulmonary vasoconstriction, and it is likely that a severely affected patient will require intubation and ventilatory support. Pharmacologic agents, including cardiovascular pressors and vasoactive agents, can be used to stabilize the patient's hemodynamics. Once the circulation has been stabilized, arterial and central venous catheters are placed to monitor cardiac output and pulmonary arterial oxygen saturation. There is debate as to whether pulmonary artery catheters, although obviously helpful in management, should be used in the setting of acute pulmonary

FIGURE 102-1 ■ Acute pulmonary embolism treatment scheme. *CT*, Computed tomography; *ECHO*, echocardiography; *ELS*, extracorporeal life support; *LMWH*, low-molecular-weight heparin; *RV*, right ventricle.

embolism, because of the risk of dislodging further thromboembolic material. The electrocardiogram is monitored, a Foley catheter is inserted for accurate recording of urine output, and blood gas levels are obtained. Patients with objectively confirmed pulmonary embolism and no contraindications for anticoagulation should receive prompt anticoagulant therapy with subcutaneous low-molecular-weight heparin, intravenous or subcutaneous unfractionated heparin, or subcutaneous fondaparinux (an inhibitor of activated factor Xa).^{19,36} For patients with suspected or confirmed heparin-induced thrombocytopenia, a non-heparin-based anticoagulant, such as lepirudin, argatroban, or bivalirudin should be used.³⁷ Although each of these individual therapies prevents propagation and formation of new thromboemboli, they rarely dissolve the existing clot. In most cases, the patient's intrinsic fibrinolytic system will lyse fresh thrombi over a period of days to weeks.³⁸ Intravenous heparin is monitored by measurement of activated partial thromboplastin times, which are maintained between 51 and 70 seconds (roughly twice that of controls) every 6 to 8 hours. The platelet count should be measured every 2 to 3 days to detect the presence of heparin-induced

thrombocytopenia. Prothrombin times are also obtained at baseline to prepare for anticoagulation with warfarin later.

Although warfarin is typically used for long-term anticoagulation after acute pulmonary embolism, several new oral anticoagulants have recently come on the market that do not require laboratory monitoring of anticoagulation (Table 102-1). They include factor Xa inhibitors, rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa), as well as the direct factor IIa (thrombin) inhibitor dabigatran (Pradaxa). All these drugs except edoxaban have been approved by the U.S. Food and Drug Administration (FDA) for the long-term treatment of deep venous thrombosis with or without pulmonary embolism, with edoxaban currently undergoing FDA scrutiny. To date, there are no known clinically validated reversal agents for rivaroxaban, apixaban, edoxaban, or dabigatran. Based on the strength of available evidence and current American College of Chest Physicians Evidence-Based Guidelines, warfarin continues to be a monitorable, reversible, and effective agent in patients with venous thromboembolism and acute pulmonary embolism, and it should remain the first-line option for

TABLE 102-1 Pharmacologic Characteristics of Direct Oral Anticoagulants

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban

long-term (3-6 month) treatment of pulmonary embolism.³⁹ However, the factor Xa inhibitors rivaroxaban and apixaban, as well as the direct thrombin inhibitor dabigatran, are each viable alternatives in patients with less than optimal INR control (targeted therapeutic range < 60%) or in whom warfarin monitoring and management is not possible.⁴⁰ Three months of warfarin anticoagulation is recommended for patients with a first-episode deep venous thrombosis related to a major reversible risk factor (i.e., recent surgery or trauma).^{41,42} Six months of warfarin anticoagulation is recommended for patients who have recurrent or unprovoked deep venous thrombosis with or without pulmonary embolism as prophylaxis against recurrent disease.^{43,44}

The natural history of the clot in survivors of acute embolic events is fragmentation and progressive lysis. It therefore follows that the addition of streptokinase, urokinase, or recombinant tissue plasminogen activator improves survival by increasing the rate of lysis of fresh thrombi in the pulmonary arterial tree. Thromboembolytic agents dissolve thrombi by activating plasminogen to plasmin. Plasmin, when in proximity to a thrombus, degrades fibrin to soluble peptides. Circulating plasmin also degrades soluble fibrinogen and, to variable degrees, factors II, V, and VIII. In addition, increased concentrations of fibrin and fibrinogen degradation products contribute to coagulopathy by both inhibiting the conversion of fibrinogen to fibrin and interfering with fibrin polymerization. The thromboembolytic agents currently approved by the FDA for the treatment of acute pulmonary embolism are streptokinase, urokinase, recombinant tissue plasminogen activator (alteplase), and tissue plasminogen activator.⁴⁵ Some new agents (so-called second-generation thrombolytics) such as reteplase, saruplase, staphylokinase, tenecteplase, and anistreplase are undergoing clinical testing.⁴⁶

Although thrombolytic therapy has been shown to increase the rate of lysis of fresh pulmonary clots more than that of heparin alone,⁴⁷ there has been little difference measured in the amount of residual thrombus between the two treatments in early studies using small cohorts of patients.^{48,49} However, four registries (MAPPET, ICOPER, RIETE, EMPEROR) comparing thrombolytic agents with intravenous (IV) heparin in acute pulmonary embolism have been large enough to detect a significant difference in the most important endpoint—mortality, particularly in patients with massive pulmonary embolism, presenting with hypotension.⁵⁰⁻⁵⁵

More recent experience suggests a trend toward better results with thrombolytic therapy because of a more rapid diminution in right ventricular afterload and dysfunction.^{56,57} Thus, thrombolytic therapy should also be considered in normotensive patients with evidence of severe right ventricular dysfunction on echocardiography. Compared with heparin therapy alone, thrombolytic agents carry a higher risk of bleeding problems, with up to 20% of patients experiencing a significant bleeding complication.^{58,59} In general, thrombolytic therapy is contraindicated in patients with intracranial hemorrhage, fresh surgical wounds, anemia, recent stroke, peptic ulcer, or bleeding dyscrasias.

Percutaneous Treatments

Percutaneous techniques to recanalize complete and partial occlusions in the pulmonary trunk or major pulmonary arteries are potentially life saving in selected patients with massive or submassive pulmonary embolism.⁶⁰ Transcatheter procedures can be performed as an alternative to thrombolysis when there are contraindications or when emergency surgical embolectomy is unavailable or contraindicated. Catheter interventions can also be performed when thrombolysis has failed to improve hemodynamics in the acute setting. The goals of catheter-based therapy include rapidly reducing pulmonary artery pressure, increasing systemic perfusion, and facilitating RV recovery.⁶¹⁻⁶³

There are three general categories of percutaneous intervention for removing emboli and decreasing thrombus burden: aspiration thrombectomy, thrombus fragmentation, and rheolytic thrombectomy. For aspiration thrombectomy, a device is used that consists of a small terminal cup attached to a flexible catheter.⁶¹ Syringe suction is applied to the cup as a thrombus is engaged. The catheter and clot are removed en masse through the venotomy site, and this process can be repeated multiple times. Thrombus fragmentation has been performed with balloon angioplasty,⁶⁴ a pigtail rotational catheter,⁴⁵ or a more advanced fragmentation device (the Amplatz catheter with an impeller housed in a capsule at the tip) driven by a compact air turbine that homogenizes thrombus by maceration and fragmentation. A metal capsule protects the vessel from the rotating impeller.⁶⁵ A third technique, the rheolytic thrombectomy technique, uses a dual-lumen catheter: one small lumen for delivery of pulsatile pressurized saline and a larger effluent or exhaust

lumen to drain the thrombus. High-velocity saline jets are injected toward the effluent lumen. This produces an area of low pressure at the tip of the catheter (Venturi effect), thereby fragmenting the thrombus and allowing it to be evacuated through the effluent lumen.^{63,66}

Recently, a new technique of suction thrombectomy with extracorporeal venovenous support (AngioVac, Angiodynamics, Latham, NY) has been described for the removal of proximal pulmonary emboli.⁶⁷ With this technique, a drainage cannula with a balloon-actuated, expandable, funnel-shaped distal tip is introduced through a femoral or right internal jugular vein and advanced under fluoroscopy to the site of embolism. The cannula is connected in circuit with an extracorporeal circulation pump attached to a second cannula inserted into the contralateral femoral vein. Venovenous bypass is instituted, and particulate matter suctioned through the inflow cannula is trapped within filters in the circuit, allowing for reinfusion of blood that is free of gross debris. This hybrid procedure is typically performed in an operating room, with thoracic surgeon and cardiologist present.⁶⁸ Successful catheter extraction of thrombus with clinically significant reduction in pulmonary arterial pressure for each of the above methods varies between 75% and 88%, with the best results achieved for proximal and main pulmonary artery embolism.^{69,70}

Acute Pulmonary Embolectomy

When contraindications preclude thrombolysis, emergency pulmonary thromboembolectomy is indicated for suitable patients with either life-threatening circulatory insufficiency from massive pulmonary embolism or submassive pulmonary embolism.⁷¹ The decision to proceed with catheter-based versus surgical embolectomy requires interdisciplinary teamwork, discussion that involves the surgeon and interventionalist, and an assessment of the local expertise. If a patient has been taken directly to the operating room without a definitive diagnosis, transesophageal or epicardial echocardiography and color Doppler mapping can confirm or refute the diagnosis in the operating room.⁷² The primary difficulty with the broad application of operative embolectomy is that it is almost impossible to determine which patients will die without intervention. An emergency pulmonary embolectomy is most feasible (because of time) and most successful in patients who ultimately may not require it, which makes it difficult to establish the efficacy of this operation. To date, no randomized trial has evaluated surgical embolectomy in patients with acute pulmonary embolism. Indications for acute surgical intervention include the following: (1) critical hemodynamic condition, with the patient deemed unlikely to survive; (2) definitive diagnosis of pulmonary embolism in the main or lobar pulmonary arteries with compromise of oxygen gas exchange; (3) unstable patients in whom thrombolytic or anticoagulation therapy is absolutely contraindicated; and (4) the presence of a large clot trapped within the right atrium or ventricle.

Acute pulmonary embolectomy was first described by Trendelenburg in 1908⁷³ using pulmonary artery and aortic occlusion, through a transthoracic approach. There

were no surviving patients. Sharp⁷⁴ performed the first successful open embolectomy, using cardiopulmonary bypass.

For pulmonary embolectomy, a median sternotomy incision is used and cardiopulmonary bypass is instituted. The procedure is best performed on a warm, beating heart, without aortic cross-clamping, cardioplegia, or fibrillatory arrest. Occluding tapes are placed around the superior and inferior vena cavae. Two polypropylene sutures are placed in the mid-pulmonary artery for traction. A longitudinal incision is made between these sutures in the main pulmonary artery trunk 1 to 2 cm distal to the valve. If necessary, the incision can be extended directly into the left pulmonary artery. Extraction is limited to directly visible emboli, which can be accomplished to the level of the lobar and segmental arteries. Fresh clot removal from subsegmental arteries may be attempted, but is often surgically difficult because of the soft, sticky, often fragmental nature of peripheral pulmonary emboli. The emboli are extracted using forceps, suction, and balloon catheters. The right pulmonary artery also can be exposed and opened between the aorta and superior vena cava to allow better exposure in segmental vessels, if necessary. A sterile pediatric bronchoscope can be used to visualize emboli in tertiary or quaternary pulmonary vessels, so that they can be cleared with balloon embolectomy or suction. After cleaning the pulmonary arterial tree lumina, the pleural spaces can be entered, and the lungs are manually compressed to dislodge small distally lodged clots, which can then be suctioned out. The pulmonary arteriotomy is then closed with a 6-0 polypropylene suture. After restarting the heart, the patient is weaned from bypass, decannulated, and closed. The aim of this operation is to remove most of the embolic material, and no attempt is made to perform an endarterectomy.

As a corollary to this operation, some groups recommend either placement of an inferior vena caval filter or caval clipping before chest closure. Greenfield has recommended placement of an inferior vena caval filter under direct visualization before closing the chest.⁷⁵ Historically, some European surgeons clipped or plicated the intrapericardial vena cava at the end of the embolectomy to prevent migration of lower body clot into the pulmonary circulation; however, this procedure is associated with stasis in the venous system in the lower body and leg swelling.⁷⁶ In most centers that offer emergency pulmonary thromboembolectomy, no caval procedure is performed in the perioperative period, and recurrent deep venous thrombosis or pulmonary embolism are treated by anticoagulation with warfarin for 6 months.⁷⁷ Percutaneously placed filters are recommended only for patients with contraindications to anticoagulation or for patients with recurrent pulmonary embolism on therapeutic anticoagulation. The cone-shaped Greenfield filter is the most widely used permanent filter in the United States, and it is associated with a lifetime recurrent embolism rate of 5% and a lifetime patency rate of 97%.^{78,79} The advent of retrievable inferior vena caval (IVC) filters appears to have lowered thresholds for IVC filter placement in the United States; however, there are few data to support or refute this claim.^{19,80} Late

complications of permanent and retrievable filters include recurrent deep venous thrombosis (21%), IVC thrombosis (2% to 10%), and IVC penetration (0.3%).⁸¹ IVC filter fractures have also been reported.⁸²

Extracorporeal Life Support

The wider availability of long-term mechanical perfusion (termed *extracorporeal life support* [ELS]) using peripheral vessel cannulation to stabilize the circulation offers another approach to life-threatening pulmonary embolism. Most pulmonary emboli, even those that are massive, will dissolve with time. ELS can be instituted outside the operating room setting and can be implemented with rapidity in institutions where preparation for its emergency use has been made. With a trained team, needed equipment, and associated supplies readily available, ELS can be implemented within 15 to 30 minutes.⁸³ For hemodynamic support during the period of a life-threatening pulmonary embolism, venoarterial extracorporeal support can be instituted and maintained for a period up to several weeks, if necessary.⁸⁴

This procedure begins with an IV heparin bolus of 1 mg/kg, followed by percutaneous or surgical cut-down of the femoral artery and femoral or internal jugular veins. If pulses are absent or weak, a larger incision is usually faster; however, because patients need heparin and have possibly received fibrinolytic drugs, a minimal wound is preferred. The tip of the venous catheter is advanced into the right atrium to obtain a flow rate of 2.5–4.0 liters/min using an emergency pump-oxygenator circuit primed with crystalloid.⁸⁵ The perfusion circuit consists of IV or arterial access tubes, a centrifugal pump, and a membrane oxygenator.⁸⁶ An electromagnetic flowmeter is placed on the arterial line, and an arterial filter is not applied. While the patient is receiving ELS, heparin is infused to maintain the activated clotting time between

150 and 180 seconds. In the initial hours after institution of ELS, activated clotting times are measured every 30 minutes, followed by every hour thereafter until decannulation. During the period of ELS support, thrombolytic drugs may be instilled directly into the pulmonary artery via a Swan-Ganz catheter to aid in clot lysis. ELS support can provide critical support to bridge an unstable patient to surgical embolectomy.⁸⁷

Once oxygenation has been stabilized and PVR has normalized, the patient is decannulated, and the cannulation sites are surgically closed. ELS is usually discontinued in the operating room because vessels should be sutured closed due to the need for heparin and long-term anticoagulation.

Results of Surgical Embolectomy for Acute Pulmonary Embolism

Mortality rates for emergency pulmonary embolectomy vary widely, between 0% and 62% (Table 102-2).^{88–108} It is difficult to compare these retrospective studies because of the difference in time in which the operations were performed, the preoperative hemodynamic state of the patient populations, and the variation in treatment plans. In general, greater surgical mortality was encountered if a patient had a preoperative cardiac arrest or required ELS support. For example, the mortality in patients who have suffered a cardiac arrest is reported in multiple series from 27% to 64% (see Table 102-2), while the mortality in patients who have not suffered cardiac arrest is reported to be between 6% and 44%. Consequently, although some groups report low mortality rates, this may be attributable to the selection of less ill patients as candidates for surgery. In patients in whom ELS is instituted during preoperative cardiac resuscitation, subsequent operative mortality ranges between 44% and 57%.^{43,85} Thus, the outcome depends largely on the

preoperative condition of the patient. Primary causes of death include brain damage, cardiac failure, uncontrollable bleeding, and sepsis. Recurrent embolism after surgery is uncommon,⁹⁶ and approximately 80% of those who survive surgery maintain normal pulmonary artery pressures and exercise tolerance. In these patients, postoperative angiograms are normal or show obstruction in less than 10% of vessels. A minority of patients who have obstruction in more than 40% of pulmonary vessels after surgery have experienced reduced pulmonary function and exercise tolerance.¹⁰⁹

CHRONIC PULMONARY THROMBOEMBOLIC DISEASE

Incidence and Natural History

The natural history of pulmonary embolism is generally total embolic resolution, or resolution leaving minimal residua, with restoration of a normal hemodynamic status. However, for unknown reasons, embolic resolution is incomplete in a small subset of patients. If the acute emboli are not lysed in 1 to 2 weeks, the embolic material becomes attached to the pulmonary arterial wall at the main pulmonary artery, lobar, segmental, or subsegmental levels.¹¹⁰ With time, the initial embolic material progressively becomes converted into connective and elastic tissue filled with endothelial and smooth muscle precursor cells as well as macrophages.^{111,112} Often, visualization of the pulmonary arteries by angiography a few weeks after unresolved pulmonary embolism reveals vessel narrowing at the site of embolic incorporation. In some patients, recanalization of some of the pulmonary arterial branches occurs, with the formation of fibrous tissue in the form of bands and webs.¹¹³ By a mechanism that is poorly understood, this chronic obstructive disease can lead to a small vessel (precapillary) arteriolar vasculopathy characterized by excessive vascular and inflammatory cell proliferation around small arterioles in the pulmonary circulation.¹¹⁴ These pulmonary microvascular changes resemble the arteriopathy observed in World Health Organization Group 1.1 or idiopathic pulmonary arterial hypertension and are gaining increased recognition as contributors to disease progression in chronic thromboembolic PH.¹¹⁵ Precapillary arteriolar vasculopathy is mostly seen in the remaining open vessels, which are subjected to long exposure at high flow. Pulmonary hypertension results when the capacitance of the remaining open bed cannot absorb the cardiac output, either because of the degree of primary obstruction by thromboembolic material and adjacent remodeling or because of the combination of a proximal obstruction and secondary small-vessel vasculopathy. The importance of pulmonary arteriolar remodeling in the development of chronic thromboembolic PH is supported by the following observations: (1) there is often a lack of correlation between elevated pulmonary arterial pressure and the degree of angiographic pulmonary vascular bed obstruction, (2) PH can progress in the absence of recurrent thromboembolism, and (3) total PVR is still significantly higher in chronic thromboembolic PH patients than in acute

pulmonary embolism patients with a similar degree of proximal vascular bed obstruction.^{116,117}

The incidence of PH caused by chronic pulmonary embolism is even more difficult to determine than that of acute pulmonary embolism. There are more than 500,000 survivors of symptomatic episodes of acute pulmonary embolism per year.¹¹⁸ The incidence of chronic thrombotic occlusion or stenosis in the population depends on which percentage of patients fails to resolve acute embolic material. One estimate is that chronic thromboembolic disease develops in only 3.8% of patients with a clinically recognized acute pulmonary embolism.⁵ If these figures are correct and only patients with symptomatic acute pulmonary emboli are counted, approximately 19,000 individuals would progress to chronic thromboembolic PH in the United States each year. However, because many (if not most) patients with a diagnosis of chronic thromboembolic disease have no antecedent history of acute embolism, the true incidence of this disorder is probably much higher.

Regardless of the exact incidence, it is clear that acute embolism and its chronic relation, fixed chronic thromboembolic occlusive disease, are much more common than is generally appreciated and are seriously underdiagnosed. In 1963, Houk and colleagues¹¹⁹ reviewed the literature of 240 cases of chronic thromboembolic obstruction of major pulmonary arteries, but found that only six cases were diagnosed correctly before death. Calculations extrapolated from mortality rates and the random incidence of major thrombotic occlusion found at autopsy supported the postulate that more than 100,000 people in the United States currently have PH that could be relieved by operation. An autopsy analysis of 13,216 patients showed pulmonary thromboembolism in 5.5% of autopsies and up to 31.3% in older patients.¹²⁰

Chronic thromboembolic PH is a disease characterized by initial thromboembolism to the pulmonary arterial tree that does not resolve itself. Whether this is due to an endothelial insult, preexisting prothrombotic state, or endothelial or smooth muscle progenitor cell trapping and remodeling is the subject of debate. No clear etiology has been defined for the majority of patients who develop chronic thromboembolic PH. Lupus anticoagulant may be detected in approximately 10% of chronic thromboembolic patients,¹²¹ and 20% carry anticardiolipin antibodies, lupus anticoagulant, or both.¹²² A recent study has demonstrated that the plasma level of factor VIII, a protein that is associated with both primary and recurrent venous thromboembolism, is elevated in 39% of patients with chronic thromboembolic PH.¹²³ Other hematologic abnormalities observed in chronic thromboembolic PH include increased resistance to thrombolysis¹²⁴ and decreased thrombomodulin levels.¹²⁵ Analyses of plasma proteins in patients with chronic thromboembolic disease have shown that fibrin from these patients is resistant to thrombolysis *in vitro*.¹²⁶ In addition, in a previous pathology series, 15% of patients had an underlying autoimmune or hematologic disorder (e.g., polycythemia vera).¹²⁷ Finally, non-O blood group types are significantly more common in patients with chronic thromboembolic PH compared to patients with idiopathic pulmonary arterial

hypertension¹²⁸ and compared with the general American and European populations (<http://www.redcross.org>).

Case reports and small series have suggested links between chronic thromboembolism and previous splenectomy, thyroid replacement therapy, permanent intravenous catheters, and ventriculoatrial shunts for the treatment of hydrocephalus or chronic inflammatory conditions, such as osteomyelitis or inflammatory bowel disease. In addition to these observations, associations with sickle cell disease, hereditary stomatocytosis, the Klippel-Trenaunay syndrome, and malignancy have been described.¹²⁹ However, the vast majority of cases of chronic thromboembolic PH are not linked with a specific coagulation defect or underlying medical condition as described earlier.

Without surgical intervention, the survival of patients with chronic thromboembolic PH is poor and is inversely related to the degree of PH at the time of diagnosis. Riedel colleagues⁶ found a 5-year survival rate of 30% among patients with a mean pulmonary artery pressure greater than 40 mm Hg at the time of diagnosis and 10% in those whose pressure exceeded 50 mm Hg. In another study, a mean pulmonary artery pressure as low as 30 mm Hg was identified as a threshold for poor prognosis.¹³⁰

Clinical Manifestations

Patients with chronic thromboembolic PH usually have subtle or nonspecific presenting symptoms. The most common symptoms are progressive exertional dyspnea and exercise intolerance.¹³¹ These symptoms are a result of elevated dead space ventilation and a limitation in cardiac output from obstruction of the pulmonary vascular bed. As the disease progresses, additional symptoms such as edema, chest pain, lightheadedness, and syncope may develop. Early in the course of thromboembolic disease, physical findings may be limited to an accentuated P2, which can be overlooked easily during the physical examination. Nonspecific chest pains occur in approximately 50% of patients with more severe PH. Hemoptysis can occur in all forms of PH and probably results from abnormally dilated vessels distended by increased intravascular pressures. Peripheral edema, early satiety, and epigastric or right upper quadrant fullness or pain can develop as the right side of the heart fails and cor pulmonale develops.

Physical signs of PH include a jugular venous pulse that is characterized by a large A wave. As the right side of the heart fails, the V wave becomes predominant. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Patients with advanced disease may be hypoxic and cyanotic. Clubbing is an uncommon finding. As the right side of the heart fails, a right atrial gallop may be auscultated, and tricuspid insufficiency develops. Because of the large pressure gradient across the tricuspid valve in PH, the murmur is high-pitched and might not exhibit respiratory variation. These findings differ from those usually observed in tricuspid valvular disease. A murmur of pulmonic regurgitation also may be detected, and a specific auscultatory

finding is a flow murmur at the back—thought to result from stenosed pulmonary vessels.¹³²

Diagnostic Evaluation of Chronic Thromboembolic Pulmonary Hypertension

Pulmonary vascular disease always must be considered in the differential diagnosis of unexplained dyspnea. The diagnostic evaluation serves three purposes: to establish the presence and severity of PH; to determine its etiology; and, if thromboembolic disease is present, to determine whether it is surgically correctible (Fig. 102-2).

Chest radiography is often unrevealing in the early stages of chronic thromboembolic PH. As the disease progresses, several radiographic abnormalities may be found. These abnormalities include peripheral lung opacities suggestive of scarring from previous infarction, cardiomegaly with dilation and hypertrophy of the right-sided chambers, and dilation of the central pulmonary arteries. Pulmonary function tests are often obtained in the evaluation of dyspnea, and they serve to exclude the presence of obstructive airways or parenchymal lung disease. There are no characteristic spirometric changes that are diagnostic of chronic thromboembolic PH. Single-breath diffusing capacity for carbon monoxide (DLCO) may be moderately reduced, and it has been reported that 20% of patients have a mild to moderate restrictive defect caused by parenchymal scarring.¹³³ Arterial blood oxygen levels may be normal even in the setting of significant PH. Most patients, however, experience a decline in PO₂ with exertion.

Transthoracic echocardiography is the first study to provide objective evidence of the presence of PH. An estimate of pulmonary artery pressure can be provided by Doppler evaluation of the tricuspid regurgitant envelope. Additional echocardiographic findings vary depending on the stage of the disease, and they include right ventricular enlargement, leftward displacement of the interventricular septum, and encroachment of the enlarged right ventricle on the left ventricular cavity with abnormal systolic and diastolic function of the left ventricle.¹³⁴ Contrast echocardiography may demonstrate a persistent foramen ovale, which is the result of high right atrial pressures opening the previously closed intraatrial communication. Once the diagnosis of PH has been established, distinguishing between major-vessel obstruction and small-vessel pulmonary vascular disease is the next critical step.

Radioisotope ventilation-perfusion (V/Q) lung scanning is the essential test for establishing the diagnosis of unresolved pulmonary thromboembolism. A normal ventilation-perfusion scan excludes the diagnosis of chronic thromboembolic PH. The V/Q scan typically demonstrates one or more mismatched segmental defects caused by obstructive thromboembolism. This is in contrast to the normal or "mottled" perfusion scan seen in patients with primary PH or other small-vessel forms of PH.¹³⁵ It is important to note that V/Q scanning can underestimate the magnitude of perfusion defects with chronic thromboembolic PH, as partial recanalization of

FIGURE 102-2 ■ Chronic thromboembolic pulmonary hypertension treatment scheme. *CT*, Computed tomography; *CTEPH*, chronic thromboembolic pulmonary hypertension; *MRI*, magnetic resonance imaging; *PH*, pulmonary hypertension; *RV*, right ventricular; *V/Q*, ventilation-perfusion.

the vessel lumen can occur, resulting in some perfusion though with significant obstruction to flow.¹³⁶

Cardiac catheterization provides essential information in the evaluation of patients with suspected thromboembolic PH. Right ventricular catheterization allows for the quantification of the severity of PH and assessment of cardiac function. Measurement of oxygen saturations in the vena cava, right ventricular chambers, and the pulmonary artery may document previously undetected left-to-right shunting. Coronary angiography and left-sided heart catheterization provide additional information about patients at risk for coronary artery or valvular disease and establish baseline measurements for cardiac output and left ventricular function. This information is crucial in the preoperative risk assessment of patients deemed candidates for pulmonary endarterectomy.

Pulmonary angiography is the gold standard for defining pulmonary vascular anatomy and is performed to identify whether chronic thromboembolic obstruction is present, to determine its location and surgical accessibility, and to rule out other diagnostic possibilities. In angiographic imaging, thrombi appear as unusual filling defects, pouches, webs, or bands, or completely thrombosed vessels that may resemble congenital absence of a vessel. Organized material along a vascular wall produces a scalloped or serrated luminal edge.¹³⁷ Despite concerns regarding the safety of performing pulmonary angiography in patients with PH, with careful monitoring, pulmonary angiography can be performed safely even in patients with severe PH.¹³⁸ Biplane imaging is preferred, offering the advantage of lateral views that provide greater anatomical detail compared with the overlapped and obscured vessel images often seen with the anterior-posterior view. Maturation, organization, and recanalization of clot produces angiographic patterns of the following: (1) pouch defects, (2) webs or bands, (3) intimal irregularities, (4) abrupt narrowing of major vessels, and (5) obstruction of main, lobar, or segmental pulmonary vessels.¹³⁹

In approximately 20% of cases, the differential diagnosis between idiopathic pulmonary arterial hypertension and distal small-vessel pulmonary thromboembolic disease is difficult to establish. In these patients, pulmonary angioscopy often may be helpful. The pulmonary angioscope is a diagnostic fiberoptic device that was developed to visualize the intima of central pulmonary arteries. It is inserted through a vascular sheath inserted in a central vein and passed through the right side of the heart into the pulmonary artery under fluoroscopic guidance. Inflation of a latex balloon affixed to the tip of the angioscope results in obstruction of blood flow in the artery and permits visualization of the arterial intima. The classic appearance of chronic pulmonary thromboembolic disease by angioscopy consists of intimal irregularity and scarring, with webbing of the vessel lumina.¹⁴⁰ The presence of embolic disease, occlusion of vessels, or the presence of gross thrombotic material also is diagnostic. In addition, percutaneous interventional approaches using intravascular ultrasound and optical coherence tomography have provided high-resolution, real-time imaging of vascular obstructions of chronic thromboembolic PH *in vivo*.¹⁴¹

More recently, multidetector computed tomography (CT) pulmonary angiography, helical CT scanning,¹⁴² single photon emission CT scanning,¹⁴³ and magnetic resonance angiography¹⁴⁴ have been used to screen patients with suspected thromboembolic disease. Although promising, none of these techniques yet provide the resolution of pulmonary angiography, particularly in visualizing thromboembolic disease in the segmental and subsegmental vessels. Features of chronic thromboembolic disease seen by these modalities include evidence of organized thrombus lining the pulmonary vessels in an eccentric fashion, enlargement of the right ventricle and central pulmonary arteries, variation in size of lobar arteries (relatively smaller in affected segments compared with uninvolved areas), and parenchymal changes compatible with pulmonary infarction. It is important to note that recent advances such as dual-energy CT,¹⁴⁵ cone-beam CT, electrocardiograph-gated 320-row area detector CT, and lung perfusion magnetic resonance imaging may change paradigms in pulmonary vascular imaging in the future.

Surgical Selection

Although previous attempts had been made, Allison and colleagues¹⁴⁶ performed the first successful pulmonary thromboendarterectomy through a sternotomy using surface hypothermia in a patient with a 12-day history of pulmonary embolism, but only fresh clots were removed and an endarterectomy was not performed. Since then, there have been many occasional surgical reports of the surgical treatment of chronic pulmonary thromboembolism,¹⁴⁷ but by far the greatest surgical experience in pulmonary endarterectomy has been at the University of California, San Diego (UCSD),^{148,149} where more than 3200 operations have been performed.

The three major reasons for considering a patient for pulmonary endarterectomy are hemodynamic, respiratory, and prophylactic. The hemodynamic goal is to prevent or ameliorate right ventricular compromise caused by PH. The respiratory objective is to improve function by the removal of a large, ventilated but unperfused physiologic dead space. The prophylactic goals are to prevent progressive right ventricular dysfunction, retrograde extension of the clot, and the prevention of secondary vasculopathic changes in the remaining patent vessels. Pulmonary endarterectomy is considered in patients who are symptomatic and have evidence of hemodynamic or ventilatory impairment at rest or with exercise. Patients undergoing surgery usually exhibit a preoperative PVR greater than 300 dyn·s/cm⁻⁵, typically in the range of 800 to 1200 dyn·s/cm⁻⁵.¹⁵⁰ Although most patients have a pulmonary artery pressure that is less than systemic, the hypertrophy of the right ventricle that occurs over time makes PH possible at suprasystemic levels. Therefore, many patients have a level of PVR in excess of 1000 dyn·s/cm⁻⁵ and suprasystemic pulmonary artery pressures. There is no upper limit of PVR level, pulmonary artery pressure, or degree of right ventricular dysfunction that excludes patients from operation. For those with milder PH, the decision to operate is based on individual circumstances. Some patients elect to

undergo surgery at this early stage of disease because of dissatisfaction with their exercise limitation or concerns about clinical deterioration in the future.

Those who choose not to pursue surgical intervention at early stages of the disease require close monitoring for progression of PH. Because of the changes that can occur, especially in the remaining patent (unaffected by clot or obstruction) pulmonary vascular bed subjected to the higher pressures and flow, pulmonary endarterectomy is usually offered to symptomatic and asymptomatic patients whenever their angiograms demonstrate significant thromboembolic disease.¹³⁹

Guiding Principles of the Operation

There are several guiding principles of the operation: (1) the endarterectomy must be bilateral, and therefore the approach is through a median sternotomy; (2) identification of the correct dissection plan is crucial; (3) perfect visualization is essential by use of circulatory arrest, usually limited to 20 minutes for each side; and (4) a complete endarterectomy is essential. The operation must be bilateral because, for PH to be a major factor, both pulmonary arteries usually are substantially involved. The only reasonable approach to both pulmonary arteries is through a median sternotomy. Historically, there were reports of unilateral operation, and occasionally this is still performed through a thoracotomy.¹⁵¹ However, the unilateral approach ignores disease on the contralateral side, subjects the patient to hemodynamic jeopardy during the clamping of the pulmonary artery, and does not allow good visibility because of the continued presence of bronchial blood flow. In addition, collateral channels develop in chronic thromboembolic PH not only through the bronchial arteries, but also from diaphragmatic, intercostal, and pleural vessels. The dissection of the lung in the pleural space via a median sternotomy, apart from bilateral access, avoids entry into the pleural cavities and allows for the ready institution of cardiopulmonary bypass.

Cardiopulmonary bypass is essential to ensure cardiovascular stability when the operation is performed and to cool the patient to allow circulatory arrest. Excellent visibility is required, in a bloodless field, to define an adequate endarterectomy plane and then follow the pulmonary endarterectomy specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure visibility.¹⁵² There have been recent reports of the performance of this operation without circulatory arrest.^{153,154} However, it should be emphasized that although endarterectomy is possible without circulatory arrest, a complete endarterectomy is not.¹⁵⁵ The circulatory arrest portions of the case are limited to the most distal portion of the endarterectomy process, deep in the subsegmental vasculature, and they are usually limited to 20 minutes for each side with restoration of flow in between.

A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in many patients, no free thrombus is

present; and on initial direct examination, the pulmonary vascular bed may appear normal. The early literature on this procedure indicates that thrombectomy often was performed without endarterectomy, and in these cases the pulmonary artery pressures did not improve, often resulting in death.

An IVC filter is always placed before surgery unless an obvious upper extremity or cardiac (e.g., intraventricular pacing wire, ventriculoatrial shunt) source is present. In the latter case, removal of any foreign material is undertaken, with alternative sites used, as with replacement of intravascular pacing leads with epicardial electrodes. Patients are treated with warfarin until the time of surgery, and this treatment is continued throughout the patient's life after surgery.

Pulmonary Endarterectomy: Surgical Technique

The technique for pulmonary endarterectomy has largely been developed by Dr. Stuart Jamieson at UCSD.¹⁵⁶ After a median sternotomy incision is made, the pericardium is incised longitudinally and attached to the wound edges. Typically the right side of the heart is enlarged, with a tense right atrium and a variable degree of tricuspid regurgitation. There is usually severe right ventricular hypertrophy, and, with critical degrees of obstruction, the patient's condition may become unstable with manipulation of the heart. Anticoagulation is achieved with the use of heparin sodium (400 U/kg, IV) administered to prolong the activated clotting time beyond 400 seconds. Full cardiopulmonary bypass is instituted with high ascending aortic cannulation and two caval cannulas. These cannulas must be inserted into the superior and inferior venae cavae sufficiently to enable subsequent opening of the right atrium. The heart is emptied on bypass, and a temporary pulmonary artery vent is placed in the midline of the main pulmonary artery, 1 cm distal to the pulmonary valve. This marks the beginning of the left pulmonary arteriotomy.

After cardiopulmonary bypass is initiated, surface cooling with both a head jacket and a cooling blanket on the operating room table is begun. The blood is cooled with the pump oxygenator. During cooling, a 10° C gradient between arterial blood and bladder or rectal temperature is maintained.¹⁵⁷ Cooling generally takes 45 minutes to 1 hour. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein. This prevents the occurrence of atrial and ventricular distention resulting from the large amount of bronchial arterial blood flow that is common with these patients. It is most convenient for the primary surgeon to stand initially on the patient's left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the right pulmonary artery from the ascending aorta. All dissection of the pulmonary arteries takes place intrapericardially, and neither pleural cavity is entered. An incision is then made in the right pulmonary artery from beneath the ascending aorta under the superior vena cava and entering the lower lobe branch of the pulmonary artery just after the takeoff of the middle lobe artery.

Any loose thrombus, if present, is removed. The endarterectomy cannot be performed in the presence of thrombus because it obscures the plane and prevents collapse of the endarterectomized specimen, hindering distal exposure. It is important to recognize that, first, an embolectomy without subsequent endarterectomy is ineffective and, second, in most patients with chronic thromboembolic hypertension, direct examination of the pulmonary vascular bed at operation generally shows no obvious embolic material. Therefore, to the inexperienced or cursory glance, the pulmonary vascular bed might appear normal, even in patients with severe chronic embolic PH. If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained, because the development of a correct plane is essential.

When the patient's temperature reaches 20° C, the aorta is cross-clamped and a single dose of cold cardioplegic solution is administered. Additional myocardial protection is obtained with the use of a cooling jacket wrapped around the heart. The entire procedure is now performed with a single aortic cross-clamp period with no further administration of cardioplegic solution. A modified cerebellar retractor is placed between the aorta and the superior vena cava. When back bleeding from bronchial collaterals obscures direct vision of the pulmonary vascular bed, thiopental is administered (500 mg to 1 g) until the electroencephalogram becomes isoelectric. Circulatory arrest is then initiated, and the patient undergoes exsanguination. It is rare that one 20-minute period for each side is exceeded. Although retrograde cerebral perfusion has been advocated for total circulatory arrest in other procedures, it is not helpful in this operation because it does not allow a completely bloodless field, and, with the short arrest times that can be achieved, it is not necessary.

Any loose thrombotic debris encountered is removed. Next, a microtome knife is used to develop the endarterectomy plane posteriorly within the media of the vessel. Dissection in the correct plane is critical because if the plane is too deep, then the pulmonary artery may perforate, with fatal results, and if the dissection plane is not deep enough, then inadequate amounts of the partially resorbed thromboembolic material will be removed. Once the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair. For the endarterectomy, gentle traction with forceps while sweeping the outer vessel wall layer away results in the progressive withdrawal of the endarterectomy specimen. The procedure is primarily performed with a long miniature sucker with a rounded tip.¹³⁹ As each lobar branch appears, it is grasped individually and the specimen is withdrawn until each segmental vessel branches again. Each of these subsegmental specimens is then extracted. Removal of each lobar and then segmental branch makes subsequent distal dissection easier. If a large mass of endarterectomized tissue begins to obscure visibility, it is excised. The entire specimen can thus be removed for a length of approximately 20 cm. The distal-most portion endarterectomy is

performed with an eversion technique. Perforation at the level of the subsegmental vessels will become completely inaccessible later, so care must be taken to remain in the plane of the media for endarterectomy. Clear visualization in a completely bloodless field provided by circulatory arrest is therefore essential during development of the distal surgical plane. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail," beyond which there is no further obstruction. Residual material should never be cut free; the entire specimen should "tail off" and come free spontaneously. Once the right-sided endarterectomy is completed, circulation is restarted and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the pulmonary artery being preserved immediately adjacent to the incision.

After completion of the repair of the right arteriotomy, the surgeon moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made from the site of the pulmonary vent hole laterally to the pericardial reflection, avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, can endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult. The left-sided dissection is virtually analogous in all respects to that accomplished on the right. The duration of circulatory arrest intervals during the performance of the left-sided dissection also is subject to the same restriction as the right. After the completion of the endarterectomy, cardiopulmonary bypass is reinstituted and warming is commenced. Methylprednisolone (500 mg IV) and mannitol (12.5 g IV) are administered, and during warming a 10° C temperature gradient is maintained between the perfusate and body temperature. If the systemic vascular resistance level is high, nitroprusside is administered to promote vasodilation and warming. The rewarming period generally takes approximately 90 minutes, but varies according to the body mass of the patient.

When the pulmonary arteriotomy has been repaired, the pulmonary artery vent is replaced at the top of the incision. The right atrium is then opened and examined unless a negative "bubble" test result before cardiopulmonary bypass reveals no persistent foramen ovale on transesophageal echocardiography. Otherwise, any intraatrial communication (present in ≈20% of patients) is closed at this point. Although tricuspid valve regurgitation is invariable in these patients and is often severe, tricuspid valve repair is not performed. Right ventricular remodeling occurs within a few days, with the return of tricuspid competence.¹⁵⁸ If other cardiac procedures are required, such as coronary artery or mitral or aortic valve surgery, these are conveniently performed during the systemic rewarming period.¹⁵⁹ Myocardial cooling is discontinued once all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. Air is evacuated from the heart, and the aortic cross-clamp is removed.

When the patient has rewarmed, cardiopulmonary bypass is discontinued. Dopamine hydrochloride is

routinely administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable hemodynamics. The cardiac output is generally high, with a low systemic vascular resistance. Temporary atrial and ventricular epicardial pacing wires are placed. Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and the administration of platelets or coagulation factors is generally unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, also the result of the previous systemic hypothermia. All patients are subjected to a maintained diuresis with the goal of reaching the patient's preoperative weight within 24 hours. Extubation is usually performed on the first postoperative day.

Thromboembolic Disease Classification and Prediction of Surgical Outcome

Four major types of pulmonary occlusive disease, based on anatomy and location of thrombus and vessel wall pathology, have been described.¹³⁹ This intraoperative classification of disease allows for the prediction of patient outcome after pulmonary endarterectomy.¹⁶⁰

1. Type 1 disease ($\approx 11\%$ of cases of thromboembolic PH; Fig. 102-3): fresh thrombus in the main or lobar pulmonary arteries. In this situation, major vessel clot is present and visible on the opening of the pulmonary arteries. This clot usually reflects main or lobar pulmonary vessel wall disease, with stasis, and fresh propagation of clot into the major pulmonary vessels.
2. Type 2 disease ($\approx 43\%$ of cases; Fig. 102-4): intimal thickening and fibrosis with or without organized thrombus proximal to segmental arteries. In these cases, only thickened intima can be seen, occasionally with webs in the main or lobar arteries.

FIGURE 102-3 ■ Surgical specimen removed from right and left pulmonary arteries. Evidence of fresh thrombus indicates type 1 disease.

3. Type 3 disease ($\approx 42\%$ of cases; Fig. 102-5): fibrosis, intimal webbing, and thickening with or without organized thrombus within distal segmental and subsegmental arteries only. This type of disease presents the most challenging surgical situation. No occlusion of vessels can be seen initially. The endarterectomy plane must be raised individually in each segmental and subsegmental branch. Type 3 disease is most often associated with presumed repetitive thrombi from indwelling catheters or ventriculoatrial shunts and sometimes represents “burned out” disease, in which most of the embolic material has been reabsorbed.
4. Type 4 disease (less than 4% of cases): microscopic distal arteriolar vasculopathy without visible thromboembolic disease. Type 4 disease does not

FIGURE 102-4 ■ Surgical specimen removed from the right and left pulmonary arteries indicates type 2 disease.

FIGURE 102-5 ■ Surgical specimen removed from right and left pulmonary arteries. In this patient with type 3 disease, the dissection plane was raised at each segmental level.

represent classic chronic thromboembolic PH and is inoperable. In this entity, there is intrinsic small-vessel disease, although secondary thrombus can occur because of stasis. Small-vessel disease may be unrelated to thromboembolic events (primary PH) or can occur in relation to thromboembolic hypertension because of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger syndrome.

We have noticed, in the last several hundred patients, an increase in the number of patients with type 3 disease (currently, $\approx 42\%$ of cases) and a decrease in the number of patients with Type 1 (currently, $\approx 11\%$ of cases) disease. Whether this reflects referral bias (i.e., difficult cases are preferentially sent to UCSD), increased recognition and diagnosis of thromboembolic PH, or a change in the presenting spectrum of disease is unclear. Nonetheless, despite seeing an increase in patients with more distal, surgically challenging disease, excellent hemodynamic and survival outcomes have been achieved at our institution.

Results of Pulmonary Endarterectomy Surgery

Although pulmonary endarterectomy is performed at several major cardiovascular centers throughout the

world, the majority of experience with this operation has been at the UCSD, where the technique of this operation was pioneered and refined. More than 3200 pulmonary endarterectomy operations have been performed at UCSD since 1970, whereas the entire reported literature on this operation (exclusive of UCSD) is approximately 2000 cases; 2400 cases have been completed at UCSD since 1997. The mean patient age of the last 1000 patients undergoing operation was 51.6 years, with a range of 8.9 to 84.8 years. There is a slight male predominance, reflecting either disease predilection, surgical bias, or both. In 40% of cases, at least one additional cardiac procedure was performed at the time of operation. Most commonly, the adjunct procedure was closure of a persistent foramen ovale or atrial septal defect (18.9%) or coronary artery bypass grafting (7.9%).¹⁵⁹

With this operation, a reduction in pulmonary pressures and resistance to normal levels and corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained.^{161,162} These changes are permanent.¹⁶³ Table 102-3 lists the most current statistics for the last 1000 patients who underwent pulmonary endarterectomy at UCSD with respect to hemodynamic improvement. Table 102-4 presents results for the same patient group stratified for thromboembolic disease classification group. Whereas before the operation more than 82.6% of the patients were in New

CO, Cardiac output; PA, pulmonary artery; PVR, pulmonary vascular resistance.

York Heart Association (NYHA) functional class III or IV in this series, at 1 year after operation, 87.6% of patients were reclassified as NYHA functional class I or II. In addition, echocardiographic studies have demonstrated that, with the elimination of chronic pressure overload, right ventricular geometry rapidly reverts toward normal.^{164,165} Right atrial and right ventricular hypertrophy and dilation regresses. Tricuspid valve function returns to normal within a few days as a result of restoration of tricuspid annular geometry after the remodeling of the right ventricle; therefore, tricuspid valve repair is not performed with this operation.¹⁵⁸

Centers from around the world are now presenting results of surgical series of pulmonary endarterectomy operations. Table 102-5 summarizes the survival and hemodynamic outcome after pulmonary endarterectomy from this growing body of surgical experience.^{149,153,154,163,165-187}

Severe reperfusion injury is the single most frequent complication after pulmonary endarterectomy, historically occurring in approximately 15% of patients, but now in a much smaller percentage of our patients ($\approx 5\%$). Of patients with reperfusion injury, the majority resolve the problem with a short period of ventilatory support and aggressive diuresis. A minority of patients with severe lung reperfusion injury require prolonged periods

of ventilatory support, whereas extreme cases require venovenous extracorporeal support for oxygenation and blood carbon dioxide removal.¹⁸⁸ Neurologic complications from circulatory arrest have mostly been eliminated by shorter circulatory arrest periods and the use of a direct cooling jacket placed around the head, which provides even cooling to the surface of the cranium. Stroke rates for the last 1000 pulmonary endarterectomy patients at UCSD is 0.2%. In the last 1000 pulmonary endarterectomy patients at UCSD, reexploration for bleeding occurred at a rate of 2.8%, and 33.9% of patients required intraoperative or postoperative blood transfusion. Despite an average duration of surgery of 6.2 hours, wound infection occurred in only 0.6% of patients.

The single greatest risk factor for operation remains the severity of pulmonary vascular resistance and the ability to lower it to a normal range at operation. Patients with high pulmonary vascular resistance with minimal vascular obstruction on angiogram (Type 4 small vessel vasculopathy indistinguishable from idiopathic pulmonary arterial hypertension) have the worst prognosis, and surgery does not correct PH in this population. Arteriolar-capillary vasculopathy without larger vessel thromboembolic disease was not influenced by blind endarterectomy of the proximal pulmonary arterial tree. The majority of early deaths after this operation are in this subgroup, and

efforts are directed at better determining who these patients are in the preoperative setting to avoid unnecessary operation.

In the UCSD experience, overall perioperative mortality was 5.4% for the entire cohort of patients, encompassing a span of more than 30 years. In the last 1000 cases, surgical mortality for pulmonary endarterectomy was 1.5%. This reflects the learning curve for safely performing this operation and the refinements in surgical technique that enhance patient outcome.

A survey of surviving patients who underwent pulmonary endarterectomy between 1970 and 1995 at UCSD has formally evaluated long-term outcome from this operation.¹⁸⁹ Questionnaires were mailed to 420 patients who had surgery more than 1 year prior, and responses were obtained from 308 patients. Survival, functional status, quality of life, and the subsequent use of medical assistance were assessed. Survival after pulmonary endarterectomy was found to be 75% at 6 years or more. This survival exceeds single- or double-lung transplant survival for thromboembolic PH. Ninety-three percent of the patients were found to be in NYHA class I or II, compared with approximately 95% of the patients being in NYHA class III or IV preoperatively. Of the working population, 62% of patients who were unemployed before operation returned to work. Patients who had undergone pulmonary endarterectomy scored several quality of life components slightly lower than normal individuals, but significantly higher than the patients before operation. Only 10% of patients used oxygen after surgery. In response to the question "How do you feel about the quality of your life since your surgery?" 77% replied much improved, and 20% replied improved. These data appear to confirm that pulmonary endarterectomy offers substantial improvement in survival, function, and quality of life.

Alternative Therapies for Chronic Thromboembolic Pulmonary Hypertension

There are patients with chronic thromboembolic PH who are not surgical candidates, because they are either (1) technically nonoperable, or (2) technically operable but have an unacceptable surgical risk. Determination of operable candidacy should be done by a center with expertise with pulmonary endarterectomy. Candidates that are deemed poor surgical candidates may be evaluated for the option of either balloon angioplasty of the pulmonary vasculature¹⁹⁰ or medical management with riociguat,¹⁹¹ the only drug currently approved by the FDA for the treatment of chronic thromboembolic PH.

In 2001, Feinstein and colleagues¹⁹² published a series of 18 patients with inoperable chronic thromboembolic PH who underwent balloon dilation of the pulmonary arteries, with variable results. More recently, Japanese investigators refined pulmonary artery balloon angioplasty by using smaller balloons, by limiting the number of balloon inflations per session to two pulmonary vascular segments, and by the use of intravascular ultrasound.^{193,194,195} An average of 4.8 sessions is needed per

patient, and severe reperfusion edema was seen in 2% of patients. Although pulmonary artery balloon angioplasty remains largely experimental in the United States, it is rapidly gaining attention for use in nonoperable patients, such as those who have incurable malignancy or are too frail to survive operation.

Recently, riociguat, a new class of oral drug and stimulator of guanylate cyclase, met the primary and secondary endpoints (increased 6-minute walk distance, improvement in World Health Organization functional class, hemodynamics, biomarkers, and quality of life) of a phase 3, multicenter, randomized, double-blind, placebo-controlled study of 261 patients with adjudicated inoperable chronic thromboembolic PH or persistent PH after pulmonary endarterectomy.¹⁹⁶ This drug was approved by the FDA in October 2013 for the treatment of inoperable chronic thromboembolic PH and persistent PH following pulmonary endarterectomy. It is important to note that pulmonary endarterectomy remains the gold standard treatment of chronic thromboembolic PH, and it is curative of this disease. Only patients deemed inoperable by an experienced pulmonary endarterectomy team or those that have residual PH after pulmonary endarterectomy should be offered riociguat.

SUMMARY

Pulmonary hypertension owing to chronic pulmonary emboli is a condition that is underrecognized and carries a poor prognosis. Pulmonary endarterectomy is considered the best treatment for chronic thromboembolic PH. The only curative therapeutic alternative to pulmonary endarterectomy is lung transplantation and heart-lung transplantation. The advantages of pulmonary endarterectomy include a lower operative mortality, better long-term results with respect to survival and quality of life, and the avoidance of chronic immunosuppressive treatment and allograft rejection. Currently, mortality rates for pulmonary endarterectomy are 1.5%, and the operation allows for sustained clinical benefit. These results make it the treatment of choice over transplantation for thromboembolic disease to the lung both in the short and long term.

Although pulmonary endarterectomy is a technically demanding operation, excellent results can be achieved. Improvements in operative technique developed over the past four decades allow pulmonary endarterectomy to be offered to patients with an acceptable mortality rate and anticipation of clinical improvement. With the increasing recognition of patients who have thromboembolic PH and the realization that pulmonary endarterectomy is a safe and effective operation for this condition, it is anticipated that this will be an expanding area of surgical therapy in the future.

CHAPTER OUTLINE

HISTORICAL BACKGROUND

PRIMARY BENIGN TUMORS

Myxomas

Definition, Incidence, and Prevalence

Morphology

Clinical Characteristics

Diagnosis

Management

Lipomas

Lipomatous Hypertrophy of the Interatrial Septum

Papillary Fibroelastoma of the Heart Valves

Rhabdomyoma

Fibroma

Paraganglioma

Hemangioma

PRIMARY MALIGNANT TUMORS

Sarcomas

Heart Transplantation

Nonsarcomatous Primary Malignant Cardiac Tumors: Lymphomas

SECONDARY METASTATIC TUMORS

Neoplastic involvement of the heart can be divided into primary cardiac tumors arising in the heart and secondary cardiac tumors that have metastasized to the heart. Primary cardiac tumors can be further stratified into benign and malignant tumors. Secondary involvement of the heart is relatively common, with 10% to 20% of patients dying of disseminated cancer having metastatic involvement of the heart or pericardium.^{1,2} Surgical resection is seldom possible or advisable for these tumors, and surgical intervention is usually limited to drainage of malignant pericardial effusions, diagnostic biopsies, or both. There are uncommon cases of metastatic disease limited to the heart for which resection is reasonable.³

Primary tumors of the heart are uncommon but not rare. In unselected autopsy series, the incidence of primary cardiac neoplasm ranges between 0.0017% and 0.19%.⁴⁻⁸ Approximately 75% of primary cardiac tumors are benign and 25% are malignant.^{2,9} Approximately 50% of the benign tumors are myxomas, and approximately 75% of the malignant tumors are sarcomas.^{2,9} The clinical incidence of these tumors is approximately 1 in 500 cardiac surgical cases and, with the exception of myxomas, most surgeons will rarely encounter primary cardiac tumors. The purpose of this chapter is to summarize useful information for the evaluation and management of patients with primary and secondary cardiac tumors and to provide a reference for additional study on these subjects.

HISTORICAL BACKGROUND

Cardiac tumors were a postmortem diagnosis until the first antemortem diagnosis of a cardiac tumor was made in 1934 when Barnes diagnosed a cardiac sarcoma using

electrocardiography and biopsy of a metastatic lymph node.¹⁰ In 1936, Beck successfully resected a teratoma external to the right ventricle,¹¹ and Mauer removed a left ventricular lipoma in 1951.¹² Treatment of cardiac tumors was profoundly influenced by two events: the introduction of cardiopulmonary bypass in 1953 by John Gibbon allowing safe and reproducible approach to the cardiac chambers and the introduction of cardiac echocardiography allowing safe and noninvasive diagnosis of an intracardiac mass. The first echocardiographic diagnosis of an intracardiac tumor was made in 1959.¹³ A large right atrial myxoma was removed by Bahnson in 1952 using caval inflow occlusion but the patient expired 24 days later.¹⁴ Crafoord in Sweden first successfully removed a left atrial myxoma in 1954 using cardiopulmonary bypass,¹⁵ and Kay in Los Angeles first removed a left ventricular myxoma in 1959.¹⁶ By 1964, 60 atrial myxomas had been removed successfully with a steady increase because of increasing safety of cardiopulmonary bypass and increased use of echocardiography for detection.¹⁷ Operations are currently routinely performed on the vast majority of patients with atrial myxoma with minimal mortality.^{9,18} Primary malignant tumors, however, continue to represent a challenge.

PRIMARY BENIGN TUMORS

Myxomas

Definition, Incidence, and Prevalence

Myxomas are the most common primary cardiac tumors. They are benign. Although they have been reported in both sexes and in all age groups, they most often occur

in women in the third to sixth decade of life. Myxomas are usually sporadic, but at least 7% occur as part of an autosomal dominant syndrome. In the latter situation, the myxoma is a component of a larger syndrome referred to as the *Carney complex*.⁶ In the Carney complex, myxomas are associated with spotty pigmentation of the skin and endocrine hyperactivity. Myxomas that arise as part of the Carney complex affect both sexes equally and at any age. They arise as single or multiple lesions in all chambers of the heart, and tend to recur after surgical excision.⁷

Morphology

Arising from the endocardium, myxomas usually extend into a cardiac chamber. They are generally polypoid, pedunculated lesions with a smooth surface that may be covered with thrombus. The tumors range in size from 1 to 15 cm, but they are most commonly about 5 cm in diameter with a weight of approximately 70 g.^{8,19-21} Myxomas are thought to arise from pluripotent mesenchymal cells. Histologically, they consist of a matrix of acid mucopolysaccharide.²² The cells are polygonal or spindle-shaped and may form capillary-like channels that can communicate with arteries and veins located at the base of the tumor.²⁰

Myxomas most commonly occur in the atria. Approximately 75% arise in the left atrium, and 15% to 20% arise in the right atrium.²⁰ Most left atrial myxomas are located on the border of the fossa ovalis, but they can originate from any place on the atrial wall. The remaining myxomas are located in the ventricles. Myxomas arising from cardiac valves are rare (Fig. 103-1).

Clinical Characteristics

Patients with myxomas can have a variety of symptoms. In the sporadic form, classic findings include emboli, congestive heart failure caused by obstruction of cardiac blood flow, and constitutional symptoms. These sequelae are related to the location, size, and mobility of the tumor.

Because most myxomas arise in the left atrium, systemic embolization is common, occurring in 30% to 50% of cases.²³⁻²⁵ Left ventricular myxomas have an even higher propensity to embolize.^{26,27} Right atrial myxomas rarely display clinical manifestations of emboli. Embolic material from myxomas can compromise blood flow to any organ, but the brain is most commonly affected. Myxoma should be included in the differential diagnosis of any systemic embolic event, and any embolic material removed should undergo histologic evaluation.

Patients with myxomas can also display signs and symptoms related to cardiac obstruction. Typically, the findings are related to the tumor's ability to impede filling of the ventricles; in such instances, signs and symptoms may mimic those of mitral or tricuspid valve stenosis. Less commonly, the tumors impede atrioventricular (AV) valve leaflet coaptation, causing valvular regurgitation. Much less frequently, ventricular tumors obstruct ventricular outflow and cause findings similar to those of aortic or pulmonic stenosis. Constitutional symptoms

FIGURE 103-1 ■ Myxomas of the heart. **A**, Echocardiography of giant left atrial myxoma. **B**, Magnetic resonance imaging of right atrial myxoma. **C**, Magnetic resonance imaging of right ventricular myxoma. **D**, Magnetic resonance imaging of left ventricular myxoma.

include fever, malaise, rash, weight loss, and myalgia. Abnormal laboratory values, including elevated erythrocyte sedimentation rate, anemia, thrombocytopenia, and an elevated C-reactive protein, are common. These constitutional symptoms and laboratory findings are not related to tumor size or location. Many patients with myxomas are however asymptomatic. The myxoma may be detected by routine screening echocardiography performed for other indications. Asymptomatic myxomas

should be excised to prevent emboli, valvular dysfunction, or constitutional symptoms.

Diagnosis

Echocardiography is the imaging modality of choice for diagnosis of myxomas. Tumor location and characteristics can be delineated by two-dimensional transthoracic echocardiography. Transesophageal echo and three-dimensional echocardiography can be used to characterize the tumor further.^{28,29} The echocardiographic appearance of myxomas is usually distinctive, but other causes of intracardiac masses must be included in the differential diagnosis. In cases of diagnostic uncertainty, magnetic resonance imaging (MRI) and computed tomography (CT) may be helpful. Final diagnosis is confirmed by pathologic examination.

Management

Surgical resection is the mainstay of treatment. The intracardiac mass is excised after establishing cardiopulmonary bypass and cardioplegic arrest. Bicaval cannulation is used for venous return. Great care must be taken to minimize manipulation of the heart before cross-clamping the aorta to reduce the risk of intraoperative tumor embolization. A variety of approaches are available for resection of left atrial tumors. In the absence of other cardiac disease, a minimally invasive or robotically assisted operation can be used to speed postoperative recovery. Intracardiac exposure is generally achieved through a lateral, longitudinal incision in the left atrium. When visualization is difficult, additional incisions in the right atrium and septum are made.

The tumor is resected en bloc. Tumors that arise from a relatively well-defined pedicle can be excised without full-thickness excision of a button of atrial wall. However, many surgeons prefer to excise a portion of the atrial wall, especially if the tumor arises from the interatrial septum or it is a broad-based tumor. Tumors of the ventricle may be resected without full-thickness excision of a portion of ventricular wall. Tumors arising from an AV valve can usually be resected without the need for valve replacement. Regardless of the site of origin, the AV valve in proximity to the tumor should be inspected for evidence of damage.

The results of surgical excision are good, with a low risk of morbidity and mortality (0% to 3%).^{9,30,31} Recurrence of atrial myxomas is infrequent. Sporadic myxomas recur in 1% to 3% of patients at an average of 2.5 years after surgery.³² The risk of recurrence of familial myxomas ranges from 12% to 20%.^{32,33} Therefore, regular echocardiographic follow-up is recommended in the latter group. When myxomas recur, they should be resected.

Lipomas

Lipomas are well-encapsulated tumors consisting of mature fat cells that can occur anywhere in the heart, but also are found in the pericardium, subendocardium, subepicardium, or intra-atrial septum.²⁰ They can also occur at any age and have no sex predilection. Lipomas are slow

growing and can attain considerable size before producing obstructive or arrhythmic symptoms. Many are asymptomatic and are discovered incidentally on routine chest roentgenogram, echocardiogram, or at surgery or autopsy.^{34,35} Subepicardial and parietal lipomas tend to compress the heart and may be associated with pericardial effusion. Subendocardial tumors can produce chamber obstruction. The right atrium and left ventricle are sites most often affected. Lipomas lying within the myocardium or septum can produce arrhythmias or conduction abnormalities.³⁶ Large tumors that produce severe symptoms should be resected. Smaller, asymptomatic tumors encountered unexpectedly during cardiac operation should be removed if excision can be performed without adding risk to the primary procedure. These tumors are not known to recur.

Lipomatous Hypertrophy of the Interatrial Septum

Nonencapsulated hypertrophy of the fat within the atrial septum is known as *lipomatous hypertrophy*.²⁰ This abnormality is more common than cardiac lipoma and is usually encountered in older, obese, or female patients as an incidental finding during a variety of cardiac imaging procedures.³⁷ Various arrhythmias and conduction disturbances have been attributed to its presence.³⁸⁻⁴⁰ The main problem posed is differentiation from a cardiac neoplasm when the lesion is discovered on echocardiography.⁴¹ After the demonstration of a mass by echocardiography, the typical T1 and T2 signal intensity of fat on MRI can usually establish a diagnosis (Fig. 103-2).^{42,43} Arrhythmias or heart block are considered by some as an indication for resection, but there is lack of data as to the long-term benefits from resection.⁴⁴

FIGURE 103-2 ■ Lipomatous hypertrophy.

Papillary Fibroelastoma of the Heart Valves

Papillary fibroelastomas are tumors that arise characteristically from the cardiac valves or adjacent endocardium.⁴⁵ Grossly, tumors are described as resembling sea anemones with frondlike projections. The AV and semilunar valves are affected with equal frequency. Ventricular fibroelastomas that occur on the left side have a high risk of stroke.⁴⁶ Papillary fibroelastomas were formerly thought to be innocuous because they were incidental findings at an autopsy. It is now known that they are capable of producing obstruction of flow, particularly coronary ostial flow, and they can embolize to the brain and produce stroke.^{46,47} They are usually asymptomatic until a critical event occurs. Now they are found more often because of the more frequent use of echocardiography. Papillary fibroelastomas of the cardiac valve should be resected whenever diagnosed because of their known tendency to produce life-threatening complications. These tumors can often be resected using minimally invasive techniques (Fig. 103-3).⁴⁶ Valve repair rather than replacement should follow the resection of these benign tumors whenever technically feasible, using conservative margins of resection. Cytomegalovirus has been recovered in these tumors, suggesting the possibility of viral induction of the tumor and chronic viral endocarditis.⁴⁴

Rhabdomyoma

Rhabdomyoma is the most frequently occurring cardiac tumor in children. It usually manifests during the first few days after birth. It is thought to be a myocardial hamartoma rather than a true neoplasm.⁴⁸ Although rhabdomyoma appears sporadically, it is associated strongly with tuberous sclerosis, a hereditary disorder

characterized by hamartomas in various organs, epilepsy, mental deficiency, and sebaceous adenomas. Fifty percent of patients with tuberous sclerosis have rhabdomyoma, but more than 50% of patients with rhabdomyoma have or will develop tuberous sclerosis.^{49,50} The exceptional patient is one with a solitary, single rhabdomyoma who does not have or develop tuberous sclerosis.

More than 90% of rhabdomyomas are multiple and occur with approximately equal frequency in both ventricles.⁵¹ The atrium is involved in fewer than 30% of patients. Pathologically, these tumors are firm, gray, and nodular and tend to project into the ventricular cavity. Micrographs show double normal-sized myocytes filled with glycogen and containing hyperchromatic nuclei and eosinophilic staining cytoplasmic granules.^{20,49} Scattered bundles of myofibrils can be seen within cells by electron microscopy.⁵¹

The most common presentation is heart failure caused by tumor obstruction of cardiac chambers or valvular orifice flow. Clinical findings can mimic valvular or subvalvular stenosis. Arrhythmias, particularly ventricular tachycardia and sudden death, can be a presenting symptom.⁴⁹ Atrial tumors can produce atrial arrhythmias.⁴⁹ The diagnosis is suggested by clinical features of tuberous sclerosis and is made by echocardiography. Rarely, no intramyocardial tumor is found in a patient with ventricular arrhythmias, and the site of rhabdomyoma is located by electrophysiologic study.⁴⁹

Early operation is recommended in patients who do not have tuberous sclerosis before 1 year of age.⁵⁰ The tumor is usually removed easily in early infancy, and some can be enucleated.⁵⁰ Unfortunately, symptomatic tumors often are both multiple and extensive, particularly in patients with tuberous sclerosis who unfortunately have a dismal long-term outlook. In such circumstances, surgery offers little benefit.

Fibroma

Fibromas are the second most common benign cardiac tumor, with over 83% occurring in children. These tumors are solitary, occur exclusively within the ventricle and the ventricular septum, and affect the sexes equally (Fig. 103-4). Fewer than 100 tumors have been reported, and most are diagnosed by the age of 2 years. These tumors are not associated with other disease, nor are they inherited. Fibromas are nonencapsulated, firm, nodular, gray-white tumors that can become bulky. They are composed of elongated fibroblasts in broad spiral bands and whirls mixed with collagen and elastin fibers. Calcium deposits or bone can occur within the tumor and occasionally are seen on radiographs.

The majority of fibromas produce symptoms through chamber obstruction, interference with contraction, or arrhythmias. Depending on size and location, such a tumor can interfere with valve function, obstruct flow paths, or cause sudden death from conduction disturbances in up to 25% of patients.⁵⁰ Intracardiac calcification on chest radiographs suggests the diagnosis, which is confirmed by echocardiogram.

Surgical excision is successful in some patients, particularly if the tumor is localized, does not involve vital

FIGURE 103-3 ■ Fibroelastoma seen through minimally invasive thoracoscopic approach.

FIGURE 103-4 ■ Fibroma. **A**, Heart showing left ventricular fibroma. **B**, Cardiac magnetic resonance imaging showing left ventricular fibroma.

structures, and can be enucleated (Fig. 103-5).⁵² However, it is not always possible to completely remove the tumor, and partial removal is only palliative, although some patients have survived many years.^{53,54} Operative mortality can be high in infants. Most cases involve adolescents and adults.⁵² Successful, complete excision is curative.⁵² Children with extensive fibromas have been treated with cardiac transplantation.⁵³

Paraganglioma

Cardiac paragangliomas arise from chromaffin cells of the sympathetic nervous system and can produce excess amounts of catecholamines, particularly norepinephrine, but usually are not hormonally active. Approximately 90% of hormonally active paragangliomas are in the adrenal glands and are referred to as *pheochromocytomas*. Fewer than 2% arise in the chest and are referred to as *hormonally active cardiac paragangliomas*, with the term *pheochromocytoma* being restricted to the adrenals. Only 32 cardiac paragangliomas had been reported by 1991.⁵⁵ The tumor predominantly affects young and middle-aged adults with an equal distribution between the sexes.

Approximately 60% of tumors occur in the roof of the left atrium. The remainder involve the interatrial septum or anterior surface of the heart.⁵⁶ The tumor is reddish-brown, soft, lobular, and consists of nests of chromatin cells (Fig. 103-6).

Hormonally active patients usually present with symptoms of uncontrolled hypertension or are found to have elevated urinary catecholamines. The tumor is usually located by scintigraphy using ¹³¹I-metaiodobenzylguanidine^{57,58} and CT scan or MRI.^{57,58} Occasionally, cardiac catheterization with differential blood chamber sampling is necessary. Because these tumors are vascular and may be near major coronary arteries, coronary arteriograms are advisable and percutaneous biopsy should be avoided.

After the tumor is located, it should be removed, using cardiopulmonary bypass with cardioplegic arrest. Hormonally active patients require preanesthetic alpha and beta blockade, and careful intraoperative and immediate postoperative monitoring. Most tumors are extremely vascular and uncontrolled operative hemorrhage has occurred.⁵⁸ Resection may require removal of the atrial or ventricular wall, or both, or a segment of a major coronary artery.⁵⁹ Explantation of the heart to allow

resection of a large left atrial paraganglioma has been attempted by Cooley and colleagues⁶⁰ and accomplished by Reardon.⁵⁹ Transplantation has been performed for nonresectable tumor. Complete excision produces cure.⁵⁹

Hemangioma

Hemangiomas of the heart are rare (24 clinical cases reported), affect all ages, and can occur anywhere within the heart.⁶¹⁻⁶³ These vascular tumors are composed of capillaries or cavernous vascular channels. Patients usually develop dyspnea, occasional arrhythmias, or signs of right heart failure.⁶⁴ Diagnosis is difficult and chest roentgenography may be abnormal, but is not specific. Echocardiography or cardiac catheterization usually but not always establishes a diagnosis of cardiac tumor by showing an intracavity filling defect.⁶⁵ CT scan and MRI should be done. Axial T2-weighted MRI should show a high signal mass caused by vascularity.⁶⁶ Coronary angiography typically shows a tumor blush and maps the blood supply to the tumor.

The tumors can be resected in asymptomatic patients, and cardiopulmonary bypass is recommended. Meticulous ligation of feeding vessels is required to prevent postoperative residual arteriovenous fistulas or intracavity communications. Partial resections have produced long-term benefits.⁶¹ Tumors rarely resolve spontaneously.⁶⁷

PRIMARY MALIGNANT TUMORS

Sarcomas

Primary cardiac malignancy is uncommon, with only 21 surgically treated cases noted in a 25-year surgical experience from 1964 to 1989, combining the experience of two large institutions, the Texas Heart Institute and the M.D. Anderson Cancer Center in Houston, Texas.⁶⁸ Even in busy centers, primary cardiac malignancy continues to challenge the diagnostic ability and surgical skills of thoracic surgeons. Our current primary cardiac sarcoma database included more than 200 patients seen over 15 years, and surgical results have begun to improve.^{9,69-74} Approximately 25% of primary cardiac tumors are malignant, and of these approximately 75% are sarcomas.⁷⁵ McAllister's survey of cardiac tumors found the most common to be angiosarcomas (31%), rhabdomyosarcomas (21%), malignant mesotheliomas (15%), and fibrosarcomas (11%).²⁰

Primary malignant cardiac tumors arise sporadically showing no inherited linkage. Although they may span the entire age spectrum, they usually occur in adults over 40 years of age. The patients usually present with symptoms of congestive heart failure, pleuritic chest pain, malaise, anorexia, and weight loss.^{76,77} The most common symptom has been dyspnea.⁷⁸ Some develop refractory arrhythmias, syncope, pericardial effusion, and tamponade.⁶⁸ The primary approach to primary cardiac sarcoma is complete surgical resection which is often a challenge. Our approach to primary cardiac sarcoma is to classify them according to location rather than cell type.

FIGURE 103-7 ■ Pulmonary artery sarcoma. **A**, Pulmonary artery sarcoma overlying computed tomographic scan. **B**, Pulmonary artery sarcoma starting at pulmonary valve.

Location generally determines presenting symptomatology and potential surgical approaches. We divide our cases into right heart, left heart, and pulmonary artery sarcomas.^{69,79}

Pulmonary artery sarcomas often present late with pulmonary artery obstruction and can be mistaken for chronic pulmonary emboli. Cardiac MR will show tissue perfusion and allow differentiation as a tumor. These tumors arise in the dorsal pulmonary artery and often involve the valve (Fig. 103-7). Complete resection rather than endarterectomy should be performed to allow maximum survival.⁷² Left heart sarcoma often presents with left heart obstruction and congestive heart failure. Surgical resection can be challenging because of the location of the posterior left atrium. We have used cardiac autotransplantation to allow full exposure, aggressive resection, and accurate reconstruction of the heart (Fig. 103-8).^{70,73,75,80} Right heart sarcomas tend to be more bulky and infiltrative and less often appear with heart failure. Our experience has been that survival is markedly affected by achieving an R0 resection, which occurs in only about one third of cases. We recommend biopsy and neoadjuvant therapy to allow shrinkage of these large and bulky tumors to improve the R0 resection rate, and we are completing a protocol of this approach (Fig. 103-9).⁷⁴ These tumors are all aggressive, and we recommend postresection chemotherapy even when R0 resection is achieved. Surgical resection and overall care of these patients is complex and is best done in centers of excellence with multidisciplinary cardiac tumor teams.

FIGURE 103-8 ■ Cardiac autotransplantation.

FIGURE 103-9 ■ Right atrial sarcoma resection and reconstruction.

Heart Transplantation

Malignant primary cardiac sarcomas often grow to a larger size until clinical detection. Extensive involvement may therefore make complete resection and reconstruction impossible. Because complete resection is necessary for improved results, cardiac transplantation has been considered in some cases.^{74,79} Twenty-eight patients were reported to have undergone transplantation as of 2000, with 21 of the tumors being malignant. The mean survival was 12 months.⁸¹ Transplantation has been used for sarcoma,⁸²⁻⁸⁴ pheochromocytoma,⁸⁵ lymphoma,⁸⁶ fibroma,⁸⁷ and myxoma.⁸⁸ Although often technically resectable by orthotopic transplantation, most benign tumors can be removed completely by experienced teams without the need for a new heart, but malignant tumors offer several other problems. Most cardiac sarcomas involve the right or left atrium and are often in areas not routinely resected for orthotopic transplantation. This may still pose an issue with getting negative margins. Many sarcomas have metastatic disease at presentation, and using a scarce donor organ in the setting of active malignancy is generally not reasonable. There is also the mortality and morbidity inherent in transplantation. With a mean survival after transplantation for malignant primary tumors of 12 months, transplantation must be considered on a case-by-case basis by a multidisciplinary team in a center of excellence.⁸¹

Nonsarcomatous Primary Malignant Cardiac Tumors: Lymphomas

Lymphomas can arise from the heart, although it is rare.⁸⁹ Most of these tumors respond to radiation and chemotherapy, and we recommend biopsy of all right atrial tumors before treatment decisions if the patient's clinical condition will allow for it. Even when complete resection is not possible, and incomplete resection is performed to relieve acute obstructive systems, radiation and chemotherapy have allowed for up to 3-year survival in some patients.

SECONDARY METASTATIC TUMORS

Approximately 10% of metastatic tumors eventually reach the heart or pericardium, and almost every type of malignant tumor has been known to do so.^{20,90} Secondary neoplasms are twenty to forty times more common than primary cardiac malignancies.⁹¹ Up to 50% of patients with leukemia develop cardiac lesions. Other cancers that commonly involve the heart include breast, lung, lymphoma, melanoma, and various sarcomas.^{91,92} Metastasis involving the pericardium, epicardium, myocardium, and endocardium roughly follows that order of frequency.^{20,90}

The most common means of spread, particularly for melanoma, sarcoma, and bronchogenic carcinoma, is hematogenous, and ultimately via coronary arteries. In addition, metastasis can reach the heart through lymphatic channels; through direct extension from adjacent lung, breast, esophageal, and thymic tumors; and from the subdiaphragmatic vena cava. The pericardium most often is involved by direct extension of thoracic cancer; the heart is the target of hematogenous or retrograde lymphatic metastasis, or both. Cardiac metastases rarely are solitary and nearly always produce multiple microscopic nests and discrete nodules of tumor cells.^{20,90} Cardiac metastases produce clinical symptoms in only about 10% of afflicted patients.⁹⁰ The most common symptom is pericardial effusion or cardiac tamponade. Occasionally, patients develop refractory arrhythmias or congestive heart failure. Chest radiographs and electrocardiograms tend to show nonspecific changes, but echocardiography is particularly useful for diagnosis of pericardial effusion, irregular pericardial thickening, or intracavity masses interfering with blood flow.

Surgical therapy is generally limited to relief of recurrent pericardial effusions or, occasionally, cardiac tamponade. In most instances, these patients have wide-spread disease with limited life expectancies. Surgical therapy is directed at providing symptomatic palliation with minimal patient discomfort and hospital stay. This is most readily accomplished via subxiphoid pericardiectomy, which can be accomplished using local anesthesia if necessary with reliable relief of symptoms, a recurrence rate of approximately 3%, and low mortality.⁹² Alternatively, a large pericardial window in the left pleural space can be created using thoracoscopy, but we would recommend this only under unusual circumstances. This can be accomplished with minimal patient discomfort, but it

does require general anesthesia with single-lung ventilation and may be poorly tolerated by patients with hemodynamic deterioration secondary to large effusions. There are rare cases of metastatic disease isolated to the heart in which resection can be considered, but this should be done only in the context of a center of excellence with the decision made by an experienced multidisciplinary team.³

THE CAUSES OF CONGENITAL HEART DISEASE: ADDITIONAL FACTORS

GENETIC ABNORMALITIES ASSOCIATED WITH CONGENITAL HEART DISEASE

CONCLUSION

Development of the functioning heart is a complex process that is essential for survival of the embryo. The mechanisms responsible for cardiovascular morphogenesis have been studied for centuries by classical embryologists and more recently by molecular developmental biologists. Major progress in the understanding of cardiac specification and morphogenesis has been made from the study of cardiovascular development in a number of invertebrate and vertebrate model systems, from *Drosophila* to mouse. The conservation of many aspects of heart development across phylogeny has provided the basis for our increased understanding of the underlying principles of cardiac development and how congenital defects of the heart arise when development goes awry. Congenital heart malformations have long been recognized to be the result of developmental abnormalities affecting cardiac morphogenesis. Developmental defects can occur at any stage of heart development, resulting in phenotypes that vary widely, from severe morphologic abnormalities resulting in early embryonic lethality to mild defects having little physiologic impact. Because of the rapid rate of information entering the field of cardiac embryology and the scope of this chapter, detailed genetic descriptions of specific morphogenetic events are not discussed. Instead, examples are given to illustrate the current paradigms in the field. For the purposes of this book, greater detail is paid to developmental

abnormalities of the heart that result in congenital heart defects in humans.

CARDIAC SPECIFICATION

Early in embryonic development, after gastrulation at approximately day 17 to day 19 in human development, cells in the lateral mesoderm adopt a cardiogenic fate. The commitment of progenitor cells in the anterior left and right lateral plate mesoderm to the cardiogenic fate relies on inductive signals from the adjacent endoderm.¹⁻⁴ Specifically, the bone morphogenetic proteins (BMPs) expressed in the endoderm adjacent to the cardiogenic precursors play a role in cardiac induction and act with other signaling factors, including those from the fibroblast growth factor (FGF) family, hedgehog, Wnt ligands, and members of the transforming growth factor (TGF) superfamily.^{3,5-10} In vertebrates, the heart-forming region is bounded by repressive signals in addition to inductive signals. Repressive signals include members of the Wnt family of secreted molecules. In the cardiogenic region, Wnt antagonists oppose the repressive signals, allowing cells to commit to a cardiogenic fate.¹¹⁻¹³

Several lines of evidence suggest that cardiogenic precursors in the lateral plate mesoderm contain prepatterned information regarding their ultimate positional

FIGURE 104-1 ■ Model of cardiogenesis. Cardiogenic precursors bilaterally positioned in the lateral plate mesoderm contain prepatterned information regarding their ultimate positional identity and cell fate, as modeled by color code (A). The convergence and fusion of the cardiac primordia form a linear heart tube (B), which undergoes rightward or D looping (C). Rightward looping appropriately aligns the cardiac chambers for morphogenesis into the mature four-chambered structure (D). (Adapted from Allen HD, Gutgesell HP, Clark EB, et al, editors: *Moss and Adams' heart disease in infants, children, and adolescents: including the fetus and young adult*, ed 6, Philadelphia, 2001, Lippincott Williams & Wilkins, p 4, Figure 1.1.)

identity and cell fate (Fig. 104-1A). Lineage analysis has demonstrated that cells in the caudal cardiogenic mesoderm contribute to the atria, whereas cells in the rostral cardiogenic mesoderm contribute to the ventricles.¹⁴ Explant experiments also demonstrate phenotypic differences between rostral and caudal precardiac mesoderm.^{15,16} However, cell transplant experiments also demonstrate that rostral-caudal fates of cardiogenic precursors remain plastic and require instructive cues from outside the cardiogenic region.¹⁷ Taken together, these results suggest that regional positional information is prepatterned in cardiogenic precursors before the development of the linear heart tube but that these positional identities appear not to be fixed until later. Several recent studies suggest that cell-type specification information, in addition to positional information, already resides in the field of cardiac progenitors. For example, precursors of both myocardial and endocardial cells can be found in the cardiogenic mesoderm, but no bipotential precursor has been identified.^{18,19}

The definitive heart and associated vascular structures receive contributions not only from the precardiac mesoderm that forms the cardiac crescent but also from two additional populations of cells. An anterior heart-forming field has been identified that lies adjacent to the crescent on its medial aspect, and that contributes to anterior structures of the outflow tract as well as to the myocardial mass of the ventricles.²⁰⁻²² In addition, the neural crest, a population of multipotential migratory cells, contributes to the outflow tract of the heart and is specifically required for outflow tract septation.

Bilaterally symmetrical cardiogenic primordia are formed from the lateral fields of mesoderm in the early embryo. The convergence and fusion of the bilateral cardiac primordia form the primitive cardiac tube in the ventral midline (see Fig. 104-1B). The anterior margins of the cardiogenic mesoderm fuse first to form the cardiac crescent at approximately day 23 of human development.¹⁵

Fusion of the bilateral cardiac primordia then occurs in a rostral to caudal direction, with sequential addition of precardiac mesoderm at the caudal end of the developing heart tube.²³⁻²⁵ The result is the formation of the primitive linear heart tube. The linear heart tube, already containing distinct myocardial and endocardial layers,

initiates contractions at approximately 4 weeks of fetal development in humans. Morphologic and molecular polarity along the heart tube (the anteroposterior axis) exists, with distinct regions from anterior to posterior of the aortic sac, conotruncus, right ventricle, left ventricle, and atria (see Fig. 104-1B).²⁶⁻²⁸

BODY-PLAN LATERALITY AND CARDIAC LOOPING

The tubular heart undergoes a morphogenetic process of rightward looping in all vertebrates. During this process, the linear heart tube is converted into an S-shaped heart with a complex, three-dimensional structure and asymmetry about the anterior-posterior, left-right, and dorsal-ventral axes (see Fig. 104-1C). Rightward looping is the visible start to the morphogenetic process that results in an asymmetrical, multichambered heart. The specificity of rightward looping is essential for the appropriate orientation of the developing cardiac chambers with one another, with the endocardial cushions that will contribute to chamber septation, and with inflow and outflow vascular connections.

Rightward looping of the heart is the first visible indication of left-right asymmetry in the developing vertebrate body plan. The consistent directionality of this process suggests a highly conserved molecular control mechanism of left-right patterning in the vertebrate embryo. This work demonstrates that significant molecular left-right differences are present in the embryo long before the visible morphogenetic event of rightward heart looping.

Early in embryonic development, during establishment of the lateral plate mesoderm, the Hensen node appears to control the genesis of left-right differences in gene expression despite its midline position. Beating cilia that project from the node undergo a counterclockwise vortex-like movement that creates a leftward flow of fluid across the Hensen node. The unidirectional ciliary movement appears to be established by the inherent molecular chirality of the ciliary protein machinery and its molecular motor on the node.²⁹⁻³¹ The flow across the node may mediate the movement of secreted molecules across the node in a leftward direction. Such molecules could then

FIGURE 104-2 ■ Molecular determination of the direction of cardiac looping. Summary of the molecular signaling pathways implicated in visceral left-right axis determination and right-handed cardiac looping. *BMP*, Bone morphogenetic protein; *Shh*, sonic hedgehog. (Adapted from Allen HD, Gutgesell HP, Clark EB, et al, editors: *Moss and Adams' heart disease in infants, children, and adolescents: including the fetus and young adult*, ed 6, Philadelphia, 2001, Lippincott Williams & Wilkins, p 9, Figure 1.5.)

function as left-sided determinants on the left side of the node. Alternatively, evenly distributed mechanosensory cilia may be specifically activated on the left side of the node by the fluid flow across the node.³² The resultant signal transduction downstream of the activated mechanosensory cilia in left-sided cells could then initiate a left-sided molecular cascade.

A molecular cascade for left-right determination has been identified, beginning with asymmetrical expression of the morphogen sonic hedgehog (*Shh*) on the left side of the node (Fig. 104-2). Sonic hedgehog is able to induce left-sided perinodal expression of the left-sided determinant *Nodal*, a member of the transforming growth factor- β (TGF- β) signaling family.^{33,34} The molecular ground state of laterality in fact appears to be right-sidedness, with the expression of the *Nodal* normally repressed by BMP signaling. *Shh* induces the left-sided expression of *Caronte*, a secreted molecule, which overcomes BMP-mediated repression of *Nodal* in the lateral plate mesoderm.³⁵⁻³⁷ Thus, left-sided *Shh* results in the expression of *Nodal* locally and at a distance, and left-sided positional information is transferred to the left lateral plate mesoderm. One result of left-sided *Nodal* expression is the left-sided induction of *Pitx2*, a homeodomain-containing protein, throughout the left lateral plate mesoderm (see Fig. 104-2). *Pitx2* expression is maintained during subsequent organogenesis on the left side of the developing heart tube, gut, and lungs.³⁸⁻⁴⁶

This cascade thereby transmits left-sided positional information from the Hensen node to the visceral organs.

Clinical Correlate of Abnormal Laterality: Heterotaxy Syndrome

The molecular hierarchy of left-right positional information establishes global left-right differences in the vertebrate body plan. Defects in the proper establishment of left-right differences of the visceral organs are generally known as heterotaxy syndrome (derived from the Greek meaning “other arrangement”) or atrial isomerism. Often, the clinical phenotype reveals a predominance of one type of sidedness. In simple terms, asplenia syndrome can be thought of as demonstrating a bilateral right-sidedness and polysplenia syndrome can be thought of as demonstrating bilateral left-sidedness. The term *situs ambiguus* is used if the sidedness cannot be determined. Not surprisingly, mutations in the genes known to have a function in the normal establishment of left-right difference can result in the heterotaxy syndromes, both in animal models and in human patients.⁴⁷

Establishment of left-right asymmetry about the Hensen node has been demonstrated to require the *inversus viscerum* (*iv*) gene, encoding left-right dynein, the force-generating component in the cilia responsible for the vortical flow across the node. Mutation in *iv*, or in other genes that contribute components to the functional ciliary motor, causes immotile cilia syndrome and a failure to generate the initial left-right asymmetry in the Hensen node.^{48,49} Absence of asymmetry about the node results in randomized expression of left-sided determinants *Nodal* and *Pitx2* in the lateral plate mesoderm.^{39,40,42,48} The phenotypic result of the failure to generate the appropriate vector for laterality information is randomization of left- and right-sidedness in the visceral organs.

Mutations in single genes can therefore result in both polysplenia and asplenia syndromes, previously thought to be distinct entities, and therefore have distinct causes. The finding that expression of left-sided determinants *Nodal* and *Pitx2* are randomized in these cases helps to explain the variability of defects seen in the heterotaxy syndromes. For example, *Pitx2* expression can be normal, presumably resulting in *situs solitus*, or reversed, presumably resulting in *situs inversus* (the left-right mirror image specification of the visceral organs).^{43,44,50} However, it can also be bilateral, absent, or a range of relative left-right levels in between.⁵⁰ This range is similar to the wide range of *situs* abnormalities of the visceral organs observed in this model and in human patients with *situs ambiguus*. It also may help explain why previous efforts to categorize the specific morphology of heart defects in cases with asplenia and polysplenia have proved so difficult.⁵¹

The importance of ciliary function in sidedness determination has led to investigations of a mouse model with primary ciliary dyskinesia via a mutated dynein gene (*Dnabc5*), which showed a 40% incidence of heterotaxy in the homozygous mutant embryos.⁵² Translational research subsequently confirmed ciliary dysfunction in 42% of congenital heart disease (CHD) patients with heterotaxy syndrome, which may contribute to respiratory problems in addition to their heart disease.⁵³

CHAMBER SPECIFICATION AND THE CARDIOGENIC TRANSCRIPTIONAL PROGRAM

There is remarkable conservation, between animal models as disparate as *Drosophila* and vertebrates, of the early transcriptional hierarchy that specifies cardiogenic fate. The *tinman* gene, encoding a homeodomain-containing transcription factor, is required for formation of the *Drosophila* dorsal vessel (the dorsal vessel in the fly is analogous to the heart in vertebrates). *Tinman* directly activates transcription of several genes, including *pannier*, a GATA transcription factor, and myocyte enhancer factor-2 (MEF-2), a MAD-box-containing transcription factor. MEF-2 and *pannier* then contribute to the downstream transcriptional activation of cardiomyocyte structural genes.⁵⁴⁻⁵⁷

Nkx2.5 is the vertebrate ortholog of the *Drosophila tinman* gene. *Nkx2.5* is expressed early in the cardiogenic mesoderm, in part a response to induction of the heart-forming region by BMPs from the endoderm.⁵⁸⁻⁶⁰ Like *tinman* in *Drosophila*, the *Nkx2.5* transcription factor plays a role in cardiogenic differentiation in vertebrates. *Nkx2.5* physically interacts with vertebrate GATA factors, and these transcription factors mutually activate one another's promoters. This establishes a positive molecular feedback loop that appears to strengthen the choice of cardiomyocyte fate. As in *Drosophila*, the GATA and MEF-2 gene families have been demonstrated to play a role in the activation of a cardiomyocyte differentiation program throughout the myocardium. In vertebrates, three GATA family members, GATA-4, -5, and -6, demonstrate expression in cardiac lineages.⁶¹ GATA factors are required for transcriptional control of several cardiac muscle structural genes. GATA family members act in cooperation with transcription factors from other families, including *Nkx2.5* and MEF-2, to regulate the expression of target genes.⁶²⁻⁶⁴ There are four MEF-2 family members in vertebrates. As in *Drosophila*, these genes appear to directly activate structural genes of myocyte differentiation. For example, mice lacking the gene for one family member, *mef2a*, die with cardiovascular abnormalities at the looping stage and fail to express a group of muscle-specific structural genes.^{65,66}

Nkx2.5 has roles in cardiogenic differentiation and in pattern formation of the vertebrate heart. The multifaceted nature of its action perhaps results from its promiscuous interactions with transcription factors of other classes. Aside from the GATA class of transcription factors, *Nkx2.5* is able to physically interact with the T-box transcription factor *Tbx5*. The *Tbx5* gene is responsible for the human autosomal dominant disorder Holt-Oram syndrome. Cardiac manifestations of the loss of one copy of *Tbx5* or *Nkx2.5* overlap and include atrial septal defects and conduction system abnormalities. *Nkx2.5* and *Tbx5* have been shown to act synergistically on the promoters of genes with high levels of expression in the atria and the conduction system, including atrial natriuretic factor and connexin 40.^{67,68}

Concomitant with the activation of a cardiomyocyte differentiation program is the development of regional

differences between the chambers of the heart. As early as the tubular heart stage, the cardiac primordia demonstrate a segmental appearance. Morphologically, five primordial segments can be identified from posterior to anterior: sinus venosus or atrium, atrioventricular canal, left ventricle, right ventricle, and outflow tract (see Fig. 104-1B). These morphologically distinct regions must be indicative of distinct transcriptional domains in the developing heart primordia. In fact, a growing number of transcription factors have been identified that demonstrate chamber-specific patterns of transcription.

The chamber-specific expression patterns of the Iroquois family member *Irx4*, a homeobox-encoding gene, suggest a role in ventricular versus atrial chamber specification. *Irx4* is expressed specifically in the developing ventricular chambers of the heart and is excluded from the developing atria.⁶⁹ *Irx4* has been demonstrated to play an important transcriptional role in the selection of ventricular fate. Loss of *Irx4* function in the ventricles results in aberrant activation of atrial gene expression, whereas ectopic expression of *Irx4* in atrial chambers results in the aberrant activation of ventricular gene expression. Further evidence for the separate genetic control of atrial and ventricular fate is demonstrated by the zebrafish mutants *lonely atrium* and *pandora*, in which the ventricular chamber fails to form but the atrial chamber appears morphologically intact.^{70,71}

The beta helix-loop-helix factors HAND1 (eHAND) and HAND2 (dHAND) have been demonstrated to play a role in determining molecular differences between the ventricles. The chamber-specific expression of *HAND1* and *HAND2* suggested that these genes may play a role in right-versus-left ventricular chamber specification. Although both *HAND1* and *HAND2* are initially coexpressed throughout the precardiac mesoderm, *HAND2* expression becomes restricted to the right ventricular precursors during cardiac looping, whereas *HAND1* becomes restricted to left ventricular and conotruncal precursors.^{72,73} Functional analysis of *hand2* has demonstrated a role in chamber formation and may provide a molecular candidate for a severe form of human coronary heart disease. Mice homozygous for a null *hand2* allele appear to lack a morphologic right ventricle.⁷³ The phenotype of the heart in this animal model is similar to human right ventricular hypoplasia, establishing *hand2* as a candidate gene for this type of human CHD.

Irx4 and the *hand* genes suggest that the specification of chamber-specific modularity lies at least in part in the transcriptional localization of single genes. However, the notion that chamber identity as a whole is specified as a result of a small number of chamber-specific modules of gene expression is simplistic. The degree to which regulation of cardiac gene expression is a highly modular process has only begun to be understood. The analysis of the promoters of single cardiac-specific genes has demonstrated that a very large number of small promoter elements are required to recapitulate normal expression patterns.⁶¹ The degree of modularity is so high that some elements drive expression in regions not previously thought to be molecularly distinct from their neighbors.⁶¹ These findings suggest that complex combinatorial networks of

transcription factors are required for the molecular regionalization of information in the developing heart.

CARDIAC SEPTATION OF THE ATRIA, VENTRICLES, ATRIOVENTRICULAR JUNCTION, AND OUTFLOW TRACT

Cardiac septation is a complex process that begins after looping morphogenesis has realigned the cardiac segments so that the right ventricle and left ventricle are located beside one another. Complete septation of the heart is not necessary for survival of the embryo, which may in part explain the high incidence of septation defects seen in clinical cardiology practice. Four major components must develop to divide the heart into separate systemic and pulmonary circulations: (1) the atrial septum that separates the right and left atria, (2) the atrioventricular junction that contributes to atrial and ventricular septation as well as to atrioventricular valve formation, (3) the ventricular septum that separates the right and left ventricles, and (4) outflow tract or infundibular septum that separates the pulmonary from the aortic outflow tract.

Recent studies have resulted in a newer paradigm of atrial septal development than that presented by classical embryology studies.⁷⁴⁻⁷⁶ The atrial septum includes septum secundum (secondary atrial septum), septum primum (primary atrial septum), and contributions from the atrioventricular cushions (Fig. 104-3). Septum secundum is an infolding in the roof of the common primitive atrium. Septum primum develops from the dorsal wall of the atrium at 5 weeks' gestation, grows toward the atrioventricular cushions as a crescentic muscular septum, and closes off the ostium primum (primary atrial communication) when it fuses with the atrioventricular cushions during the sixth week of fetal development. Septum primum carries a "cap" of distinct mesenchymal tissue along its leading edge that is critical for fusion of the primary atrial septum with the atrioventricular cushions.⁷⁴ As septum primum grows toward the atrioventricular cushions and divides the atria, it develops fenestrations that coalesce into the ostium secundum (secondary foramen) and allow continued mixing of blood at the atrial level in the fetus.

Like the atrial septum, the ventricular septum is a complex structure that includes components derived from the atrioventricular cushions, the muscular ventricular septum, and the conal (infundibular) septum. In the early stages just after looping (31 to 35 days in the human), the muscular ventricular septum is a ridge of myocardium corresponding to the furrow of the primary fold on the outer curvature of the heart and separating the primitive left ventricle and primitive right ventricle.⁷⁷ In mammals, the muscular septum develops from a ridge of infolded compact myocardium.⁷⁸ As the heart grows markedly in size along the outer curvature, the muscular septum grows concordantly with the ventricles.²⁶ The muscular septum fuses with the endocardial cushions of the atrioventricular junction and with the outflow tract to completely separate the right and left ventricles.

FIGURE 104-3 ■ Atrial septal development. The developing atrial septum has contributions from the septum secundum, the septum primum, and the atrioventricular (AV) cushions. **A**, Septum secundum ("atrial roof") is an infolding in the roof of the primitive common atrium. **B**, Septum primum (PS) grows from septum secundum toward the AV cushions (sAVC and iAVC), carrying with it a "cap" of mesenchymal tissue that is critical for the fusion of PS with the cushions. **C**, As PS closes off the primary interatrial communication (pf in **B**), fenestrations develop (sf in **B**) and coalesce into the foramen ovale (sf in **C**), which allows the shunting of blood at the atrial level that is necessary in the fetal circulation. DM, Dorsal mesocardium; DMP, dorsal mesenchymal protrusion. (From Wessels A, Anderson RH, Markwald RR, et al: Atrial development in the human heart: an immunohistochemical study with emphasis on the role of mesenchymal tissues. *Anat Rec* 259[3]:288-300, 2000.)

The atrioventricular junction (canal) segment of the developing heart initially connects the primitive atrium exclusively to the left ventricle (see Fig. 104-1C). Complex remodeling must occur to allow inflow from the atrium directly into both right and left ventricles (see Fig. 104-1D). In addition to establishing continuity between the right atrium and the right ventricle, the atrioventricular junction gives rise to the endocardial cushions that will form the atrioventricular valves. (Endocardial cushions also form in the outflow tract and contribute to the semilunar valves and septation of the outflow tract.) The superior and inferior atrioventricular cushions fuse in the midline to form the atrioventricular septum, with resultant separation of the inflow into mitral (left-side) and tricuspid (right-side) components. The mesenchyme of the atrioventricular junction contributes to the portion of the atrial septum just proximal to the atrioventricular valves by fusing with the primary atrial septum. In addition, the atrioventricular septum mesenchyme forms the inlet portion of the ventricular septum (between the atrioventricular valves).

The growth and maturation of the endocardial cushions has been studied at the molecular level. Cardiac cushions begin as localized thickenings of the extracellular matrix between the endocardial and myocardial layers of the primitive heart tube, termed the *cardiac jelly* (Fig. 104-4).⁷³ The cushions begin as acellular structures that become populated by cells that have undergone a transformation from endothelium to mesenchyme. JB3 is

FIGURE 104-4 ■ Cushion development. The endocardial cushions appear in the atrioventricular (AV) junction (AV canal) and in the outflow tract (conus and truncus) after looping of the heart tube. The superior AV cushion (4) is contiguous with the cushions of the outflow tract (3, 3a, 2, 2a, 1, 1a) along the inner curvature of the heart. Cushion tissue contributes to the formation of the valves and also to septation of the heart. The inner curvature undergoes significant remodeling and participates in myocardialization of the cushions (arrows). (From Harvey RP, Rosenthal N, editors: *Heart development*, San Diego, 1999, Academic Press, p 171.)

an antibody that recognizes fibrillin-2,⁷⁹ and, in the heart, it recognizes only the subset of cells (JB3+) that have the potential to undergo the endothelium-to-mesenchyme transformation in the cushions.⁸⁰ The mesenchymal transformation is mediated by the myocardium of the atrioventricular junction via a number of molecules including BMP-2, BMP-4, and neuregulin, an epidermal growth factor-like molecule, as well as the homeobox-containing transcription factor *Msx-2*.⁸¹⁻⁸³ ES proteins that form complexes with fibronectin are also present in the developing cushions and appear important for the regulation of the mesenchymal transformation.^{80,81}

Contributions from the endocardial cushions and the cardiac neural crest are required for outflow tract septation (Fig. 104-5). The endocardial cushions of the

atrioventricular junction and the outflow tract are in physical continuity through the superior atrioventricular cushion, which extends along the inner curvature of the heart.⁸⁰ Extensive remodeling of the inner curvature occurs so as to connect the right atrium to the right ventricle and the left ventricle to the aorta.⁸⁴ Septation of the outflow tract results from the development of two structures. Below the level of the semilunar valves, the conal septum (infundibular septum or muscular outflow tract septum) develops from myocardialization of the outflow tract cushions, a process that also involves contributions from the cardiac neural crest and the epicardium.⁸⁴ Above the level of the semilunar valves, the aorticopulmonary septum grows from the aortic sac toward the heart to separate the pulmonary from the aortic outflow tracts.

The three components of the ventricular septum (the inlet and the muscular and conal septa) must join together to completely separate the ventricles. The region of the membranous ventricular septum in the adult heart is the approximate location where these three components join. This finding suggests that a defect in the development of either the inlet or the muscular or conal septa can result in a ventricular septal defect, suggesting a mechanistic rationale for the high frequency of defects at this anatomic location.

Clinical Correlates of Abnormal Chamber Septation

The term *common atrioventricular canal* (also called endocardial cushion defect or atrioventricular septal defect) refers to a spectrum of lesions that have improper development of the atrioventricular junction as the underlying developmental abnormality. In such cases, the atrioventricular junction has failed to undergo its normal septation and formation of separate atrioventricular valves, leaving a common atrioventricular valve providing inflow to both ventricles. The atrioventricular cushion contributions to atrial and ventricular septation are also abnormal, resulting in atrial septal defect of the ostium primum type and ventricular septal defect of the inlet (atrioventricular canal) type. This defect is reminiscent of the structure of the developing heart prior to atrioventricular junction septation by the developing endocardial cushions. Genes required for normal development of the atrioventricular endocardial cushions can result in common atrioventricular canal when mutated in a mouse model, as demonstrated by the *ALK3* conditional receptor knockout.⁸⁵ Common atrioventricular canal can therefore be conceptualized as a developmental arrest, in which chamber septation fails to progress past the common atrioventricular junction.

Although complete common atrioventricular canal accounts for only 7.3% of all congenital malformations,⁸⁶ it is observed in approximately 40% of patients with trisomy 21 (Down syndrome).⁸⁷ The epidemiologic data suggest that a gene important for the development of the atrioventricular junction resides on chromosome 21. To date, no single gene on chromosome 21 has been implicated in the genesis of common atrioventricular canal.⁸⁸

FIGURE 104-5 ■ Development of neural crest, anterior heart field, and outflow tract. **A**, The cardiac neural crest migrates into pharyngeal arches 3, 4, and 6, where it plays a crucial role in the patterning of the paired aortic arch arteries by preventing the regression of aortic arch arteries 3, 4, and 6, the precursors of the definitive great arteries. **B**, The anterior heart field is a recently described and separate migratory population of cells that originate near the second pharyngeal arch and contribute to cardiac outflow tract development. **C**, The neural crest cells condense into two prongs that insert into the endocardial cushions of the developing outflow tract. The third aortic arch arteries (L3 and R3) give rise to the right and left carotid arteries. The left fourth arch artery (L4) becomes part of the definitive aortic arch, and the right fourth arch artery (R4) contributes to the proximal right subclavian artery. The left sixth aortic arch artery (L6) forms the ductus arteriosus. DAo, Descending aorta; PT, pulmonary trunk; ST, systemic trunk. (**A** and **C** from Harvey RP, Rosenthal N, editors: *Heart development*, San Diego, 1999, Academic Press, pp 180, 182; **B** modified from Waldo KL, Kumiski DH, Wallis KT, et al: Conotruncal myocardium arises from a secondary heart field. *Development* 128:3179–3188, 2001.)

Isolated atrial septal defects are one of the most common congenital defects of the heart in humans. Secundum atrial septal defects result from a deficiency of septum primum in closing off the ostium secundum. Atrial septal defects are also frequently found in association with clinical syndromes. Secundum atrial septal defects are the most common structural defect resulting from the loss of one copy of the *Tbx5* gene in Holt-Oram syndrome, an autosomal dominant disorder.^{89,90} Mutations in the *Nkx2.5* gene have been linked to autosomal dominant secundum atrial septal defects,^{91,92} and more recently, mutations in the *GATA-4* gene have also been linked to secundum atrial septal defects.⁹³ The finding that *Tbx5*, *Nkx2.5*, and *GATA-4* all interact to regulate the expression of genes necessary for atrial septal development suggests that candidate genes for secundum atrial

septal defects may lie downstream of these important transcription factors.

OUTFLOW TRACT DEVELOPMENT: ANTERIOR HEART FIELD AND CARDIAC NEURAL CREST

Although the vertebrate heart develops primarily from the precardiac mesoderm (the cardiac crescent), two other cell populations, the anterior heart field and the cardiac neural crest, are critical for normal outflow tract development.^{20-22,94}

The existence of the anterior heart field was suspected 30 years ago, when Viragh and Challice⁹⁵ observed the

transformation of epithelial cells to myocardial cells at the arterial pole of the developing mouse heart. De la Cruz and colleagues⁹⁶ used marking studies in living chick embryos to demonstrate that the distal outflow tract was a late addition to the developing heart. A series of recent studies show that a population of cells in the anterior mesoderm adjacent to the aortic sac (see Fig. 104-5B), distinct from both the lateral cardiogenic mesoderm and the cardiac neural crest, contribute to the myocardium of the outflow tract in both avian^{21,22} and murine²⁰ models. In the murine model, the anterior heart field contributions extend past the outflow tract and also contribute to the developing right ventricle to the level of the interventricular septum.^{28,97} This finding may ultimately help explain observed gene expression differences between the right and left ventricles.

The cardiac outflow tract is initially a tubular structure connecting the primitive right ventricle to the aortic sac, and it must undergo septation to form the pulmonary artery and the aorta. In addition, the outflow tract must gain continuity with the primitive left ventricle. This occurs by a process termed *wedging*, in which the subaortic conus is remodeled to allow the aortic valve to reach its normal adult position between the tricuspid and mitral valves. This process establishes fibrous continuity of the mitral and aortic valves.⁹⁸ The aorticopulmonary septum develops from the aortic sac mesenchyme and grows into the outflow tract, where it interacts with neural crest-derived cells in the endocardial cushions, ultimately dividing the outflow tract into the aorta and the pulmonary artery.⁹³

The cardiac outflow tract receives a large contribution of cells from the neural crest, a population of migratory pluripotent cells that arise adjacent to the developing neural tube. The cardiac neural crest is a subpopulation of the neural crest that originates from between the midotic placode to the third somite (see Fig. 104-5A).⁹⁹ These cells migrate into the developing third, fourth, and sixth pharyngeal arches, where they interact with the third, fourth, and sixth aortic arch vessels, the progenitors of the definitive great arteries (aorta, carotid, and subclavian arteries, main pulmonary artery, and ductus arteriosus). The aortic arch vessels develop as symmetrically paired structures, but they undergo a highly specific and asymmetrical program of resorption, retaining the normal left aortic arch. The cardiac neural crest does not play a role in the formation of the aortic arch vessels but rather stabilizes the arch vessels and prevents their regression (see Fig. 104-5C).¹⁰⁰ A subpopulation of the cardiac neural crest migrates farther from the pharyngeal arches to the heart, where it forms the cardiac ganglia, participates in the septation of the outflow tract, and contributes to the formation of the semilunar valves.¹⁰¹ Neural crest also interacts with the pharyngeal arch mesenchyme to form the thymus, thyroid, and parathyroid glands.

Animal models of neural crest defects have been useful in determining the cause of some congenital heart malformations. Experimental ablation of the neural crest in avian embryos¹⁰² demonstrated abnormal development of the heart and great arteries, as well as abnormalities of the glandular derivatives of the pharyngeal arches and pouches (i.e., the thymus, thyroid, and parathyroid

glands).⁹⁴ Specifically, defects of the embryonic outflow tract were observed in embryos after neural crest ablation, including persistent truncus arteriosus, double-outlet right ventricle, and tetralogy of Fallot. Ventricular septal defects of the infundibular septum were also common.¹⁰³ Interestingly, defects of the inflow portion of the heart were occasionally described as well, including double-inlet left ventricle, straddling tricuspid valve, and tricuspid atresia, and they occurred in association with outflow defects.¹⁰³ Furthermore, abnormal aortic arch patterning occurred in virtually all embryos after neural crest ablation.¹⁰³⁻¹⁰⁵ The arch abnormalities demonstrated great variability and included various types of interrupted aortic arch.

Murine models with cardiac phenotypes reminiscent of neural crest ablation include the *Splotch* mouse, bearing a mutation in the *Pax3* homeobox gene. *Splotch* homozygotes demonstrate persistent truncus arteriosus and aortic arch anomalies as well as anomalies of the thymus, thyroid, and parathyroid glands. The homozygous mutation is lethal at embryonic day 14.¹⁰⁶ The *Patch* mutant mouse, bearing a deletion of a portion of chromosome 5, also demonstrates craniofacial, thymic, and outflow tract abnormalities, including arch patterning anomalies.¹⁰⁷ Initial efforts to understand this phenotype focused on the deletion of the gene for platelet-derived growth factor receptor (PDGFR). However, mice homozygous for a PDGFR-targeted null mutation do not consistently demonstrate cardiac anomalies, suggesting that other genes deleted in the *Patch* mutant must contribute to the cardiac phenotype.^{107a}

Retinoic acid, the active derivative of vitamin A, has been shown to play an important role in outflow tract development. Knockouts of the retinoic acid receptor in mice produce phenotypes reminiscent of neural crest ablation. There are two families of receptors, RAR and RXR, and each family contains three isoforms. Single-isoform knockouts produce no morphologic defects; however, double mutants of RAR and RXR produce outflow tract defects (persistent truncus arteriosus, double-outlet right ventricle, and arch anomalies), as well as craniofacial, thymic, thyroid, and parathyroid anomalies.^{88,107} If vitamin A is administered, the cardiac phenotype may be rescued.¹⁰⁸ This suggests a role for retinoic acid signaling in neural crest migration and cardiac development.

Clinical Correlates of Abnormal Outflow Tract Development: DiGeorge Syndrome and 22q11 Deletion

DiGeorge syndrome is an autosomal dominant disorder whose phenotype includes cardiac defects of the outflow tract—in particular, interrupted aortic arch, persistent truncus arteriosus, tetralogy of Fallot, and aortic arch anomalies. The syndrome also includes parathyroid hypoplasia with resultant hypocalcemia, thymic hypoplasia with resultant T cell deficit, and cleft palate and other craniofacial abnormalities. There are phenotypic similarities between DiGeorge, Takao (conotruncal anomaly face syndrome), and Shprintzen (velocardiofacial) syndromes, and, in fact, the same molecular lesion is present

in all three syndromes: deletion of 22q11. *CATCH* has been proposed as an acronym for the phenotype associated with these syndromes (cardiac defects, abnormal facies, T cell deficit, cleft palate, hypocalcemia).^{109,110} The phenotype demonstrates considerable variability between patients. The 22q11 deletion is the most common deletion in humans, occurring in 1 of 4000 live births¹¹¹ with an average of 30 genes removed, although smaller and larger deletions are not infrequent.⁹⁷

A vigorous search for candidate genes residing in the commonly deleted portion of human chromosome 22 has recently yielded some success in elucidating the molecular underpinnings of the cardiac defects. Mouse models with deletions of the region of chromosome 16 syntenic to human chromosomal region 22q11 have been used to identify and test candidate genes.¹⁰⁷ Three independent groups have reported that haploinsufficiency of the T-box transcription factor gene *Tbx1* results in cardiac phenotypes consistent with DiGeorge syndrome.¹¹²⁻¹¹⁴ However, not a single point mutation has been identified in any patient with DiGeorge syndrome; the phenotype in humans may require larger genetic alterations. The clinical variability seen among patients with DiGeorge syndrome has several possible sources, including variability in the size of the deletion, sensitivity to gene dosage from modifying genes (genetic background), and epigenetic factors. One study demonstrated that a targeted deletion of *Tbx1* in mice caused abnormal aortic arch patterning in 50% of embryos, implicating sensitivity to gene dosage in the variability of the DiGeorge phenotype.¹¹⁴ When a larger deletion containing additional genes was studied, the mice showed parathyroid hypoplasia, thymic insufficiency, and a higher perinatal lethality, implicating deletion size. Another group demonstrated abnormal development of the fourth aortic arch in mice heterozygous for a *Tbx1* deletion.¹¹³ Homozygous mutants were embryonic lethal with obliteration of the third, fourth and sixth arches.¹¹³ In this model, *Tbx1* haploinsufficient animals did not display thymic, parathyroid, or facial anomalies, again suggesting that a multiple gene deletion is required for the full clinical features of DiGeorge syndrome.¹¹³

THE CAUSES OF CONGENITAL HEART DISEASE: ADDITIONAL FACTORS

The genetic programs underlying heart development are beginning to be elucidated, but the complexity of the developmental process has made progress painstaking. Although these genetic abnormalities in animal models do correlate to certain forms of heart disease, other experimental models use variations in blood flow to produce structural heart abnormalities. An intriguing series of experiments in chick embryos used ligation of the left atrial appendage to produce a hypoplastic left heart syndrome phenotype.¹¹⁵ Subsequent work sequentially ligating the left atrial appendage and then the right atrial appendage demonstrated rescue of the hypoplastic left heart phenotype during embryonic development.¹¹⁵ These studies are suggestive that fetal interventional strategies¹¹⁶ and early surgical repair may positively impact heart development and chamber growth.

The interaction between genetic factors and environmental factors contributing to CHD is not yet fully understood. Observations of teratogen exposure such as thalidomide or retinoids producing congenital heart defects have been described for years.¹¹⁷ Hypoplastic left heart syndrome has been demonstrated to have a genetic component,¹¹⁸ but a geographic spatial analysis of cases of hypoplastic left heart cases in Baltimore, MD, demonstrated a cluster of cases near a region of industrial land with environmental exposures to solvents.¹¹⁹ Complex interactions between genetic predisposition and environmental insult may contribute to the phenotypic variability of congenital heart malformations.

GENETIC ABNORMALITIES ASSOCIATED WITH CONGENITAL HEART DISEASE

In the first portion of this chapter, developmental mechanisms critical for normal heart development were reviewed. The complexity of these processes has resulted in slow painstaking progress in the understanding of specific genetic abnormalities that are associated with CHD. Table 104-1 provides a list of single gene and chromosomal region abnormalities that have a strong association with congenital heart malformations. Aneuploidy syndromes are also known to be associated with CHD. Specifically, trisomy 21 (Down syndrome) has a 40% to 50% chance of associated CHD, most commonly atrioventricular canal defects; atrial septal defect, ventricular septal defect, patent ductus arteriosus, and tetralogy of Fallot may also be seen. Turner syndrome (monosomy, 45X0) has an association of left heart obstructive lesions including coarctation, bicuspid aortic valve, and hypoplastic left heart syndrome. Trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome) are associated with atrial septal defect, ventricular septal defect, patent ductus arteriosus, and polyvalvular disease in 80% to 100% of patients.¹²⁰

CONCLUSION

This chapter demonstrates some of the progress that has been made in the molecular understanding of embryonic heart development and how specific structural defects of the heart arise when the activity of single genes is interrupted. Hemodynamic and environmental factors may also contribute to malformations of the heart, and the broad range of phenotypes may be a result of complex interactions between genes, blood flow, and exposures. Details of cardiac specification and development continue to be elucidated, and it is the hope that a better understanding of the genetic mechanisms involved in heart formation will improve the care of patients with CHD.

SEGMENTAL ANATOMY

Stephen P. Sanders

CHAPTER OUTLINE

VISCERAL SITUS

LOCATION OF THE HEART

SEGMENTAL ANALYSIS

Segmental Situs

Segmental Alignments

Segmental Connections

Disharmony between Situs and Alignment

Examples of Segmental Analysis

SUMMARY

The heart is a complex organ. It is difficult to understand the anatomy of the heart, particularly when abnormal, and it is even more difficult to describe it clearly and succinctly. Yet this is the goal of the diagnostician cardiologist: to understand and describe the anatomy of a defective heart in a way that colleagues will comprehend sufficiently to be able to contribute meaningfully to the care of the patient. Another objective is to learn about the behavior of the various defects: occurrence rate, natural history, response to treatment, and long-term prospects. Finally, discovery of the causes and developmental mechanisms of heart defects is of great interest. These objectives require a system of analysis and naming that facilitates data gathering and communication of information.

The system of nomenclature should have certain characteristics if it is to be useful. First, the name should be descriptive and convey a picture of the defect. Who can remember the meaning of type 1B? On the other hand, tricuspid atresia with normally related great arteries and pulmonary stenosis is clear. Second, names should be unambiguous. Each name should refer to only one defect. It is less of a problem for a defect to have more than one name, as long as they map only to the same defect. For example, it makes little difference whether one uses the terms *membranous*, *perimembranous*, or *paramembranous ventricular septal defect*. They all refer to, and can be mapped to, the same type of ventricular septal defect. A problem arises if one calls a membranous defect *muscular* or *subpulmonary*, because these names refer to other types of defects as well. This would be hopelessly confusing because one name could refer to multiple types of defects. Third, the system of names should be inclusive. There should be a name for all defects, even rare ones. A large “other” category makes it hard to find rare defects, which can be highly informative regarding cause or developmental mechanism. Finally, the system must be capable of evolution and growth while remaining consistent.

The language used to describe the heart is an integral part of the analysis process. An effective way to discuss

the language of the heart is to describe a process for analyzing the heart. This process is called the “segmental approach to cardiac analysis and diagnosis.”¹⁻³ Why a segmental approach? The task of elucidating cardiac anatomy is made simpler by analyzing the cardiac segments separately and then constructing a synthesis or comprehensive diagnosis.

The heart is one of many organs in the abdomen and thorax. Analysis of the organization of these other organs provides a context for understanding and describing heart defects.

VISCERAL SITUS

The external bilateral symmetry of the human body hides the asymmetry of most internal organs. In the usual arrangement, called *situs solitus*, the left lung is bilobed and somewhat smaller than the trilobed right lung; this is apparent from the branching pattern of the bronchi. The abdomen contains several unpaired and lateralized organs, including the right-sided liver and gall bladder and the left-sided spleen and stomach. The normal rotation of the intestine places the caecum and appendix in the right lower quadrant and the sigmoid colon on the left. Rare individuals have inverted or mirror-image organization of the thoracic and abdominal viscera called *situs inversus*, which is inversion of the usual arrangement or *situs solitus*. In anatomy, inversion means left-right mirror imagery with no superior-inferior (cranial-caudal) or anterior-posterior (ventral-dorsal) change.

Laterality information is transmitted to the lateral plate mesoderm, the source of the viscera including the heart, around the time of gastrulation by the action of cilia in the node at the cranial end of the primitive streak.⁴ A cascade of transcription factors culminating in expression of *Pitx2* induces left-sided features in derivatives of the left lateral plate. Apparently, the absence of these factors leads to right-sided features in right lateral plate derivatives. The atria are lateralized structures whose

development is strongly influenced by the left-right gene regulatory networks (the left atrium, pulmonary vein, and atrial septal structures express *Pitx2c*, but right atrial structures do not⁵). Consequently, visceral and atrial situs are closely linked. In fact, the linkage is so tight that the term *visceroatrial situs* is often used to describe both at once.

The relationship between visceral situs and ventricular and outflow development is a little less strong. It is unknown how gene regulatory networks influence ventricular looping and development of the outflow and aortic sac derivatives.

Heterotaxy syndromes, abnormal symmetry and placement of usually asymmetrical and lateralized organs, result from defective or failed establishment of the left-right body axis. Abnormal atrial development is almost uniform in these conditions, whereas defective ventricular and outflow development is frequent but more variable. Heterotaxy syndromes are characterized by variability and unpredictability, although patterns of visceral and cardiac anatomy can be recognized. The concepts of “bilateral left sidedness” and “bilateral right sidedness” are useful mnemonic devices to help recall associations, but they should not be taken too seriously. These concepts probably apply best to the airways and lungs; symmetrical bronchi and lung lobation are

frequently encountered (Fig. 105-1). The liver lobation is often symmetrical, but duplication of the gall bladder rarely occurs. The spleen might be absent or multiple, but never duplicated on opposite sides of the abdomen. Similarly, the asplenia and polysplenia syndromes are often associated with particular combinations of findings, but the watchword is variability.

LOCATION OF THE HEART

The heart can be in the left chest with the apex to the left (levocardia), in the right chest with the apex to the right (dextrocardia), or in the midline with the apex down (mesocardia; Fig. 105-2). In some cases, the heart is partially or completely outside the chest (partial or complete ectopia cordis). It can be located partially or completely outside the body through a cleft in the sternum, predominantly in the abdomen, or even the neck. If the right lung is hypoplastic, or if there is a space occupying lesion in the left chest, the heart is often positioned in the right chest, but the apex points to the left or inferiorly (Fig. 105-3). This has been called *dextroposition* or *secondary dextrocardia*, as opposed to primary dextrocardia with a rightward apex. The implications of dextroposition differ from those of dextrocardia both for imaging the

FIGURE 105-1 ■ Coronal magnetic resonance images in patients with heterotaxy syndrome. **A**, Symmetrical hyparterial bronchi, both of left-sided morphology (long bronchi with the first branch some distance from the carina), in a patient with polysplenia syndrome. The right (white arrow) and left (yellow arrow) pulmonary arteries are above the ipsilateral bronchus. **B**, Symmetrical hepatic veins (arrows) draining separately into the common atrium (A) in the same patient with polysplenia. (Directional marker applies to all three images.) **C**, Multiple spleens (white outline) on the right side of the abdomen in a patient with right-sided polysplenia. In our autopsy series, right polysplenia is slightly more frequent than left polysplenia. The right kidney (white arrow) is seen medial and inferior to the spleens. The liver (Li) is left-sided. L, Left; S, superior.

FIGURE 105-2 ■ Magnetic resonance images obtained using a steady-state free precession sequence reformatted in coronal plane showing: **A**, Dextrocardia with the apex of the heart to the right. **B**, Mesocardia with the apices of the ventricles directed inferiorly. **C**, Levocardia with the apex of the heart to the left. Directional marker applies to all three images. L, Left; S, superior.

FIGURE 105-3 ■ A frontal view of a three-dimensional volumetric reconstruction of a magnetic resonance angiogram in a patient with scimitar syndrome. A portion of the hypoplastic right lung is seen below the heart, which is displaced into the right chest exposing virtually all the left lung. The apices of the right (white arrowhead) and left (yellow arrowhead) ventricles point left and inferior, indicating a nearly normal orientation of the heart. A sequestration artery (arrows) originates from the descending aorta and enters the base of the right lung. L, Left; S, superior.

heart and for associated diagnoses. Dextroposition or secondary dextrocardia is associated with scimitar syndrome, right lung hypoplasia, and noncardiac diagnoses such as diaphragmatic hernia. The orientation of the heart is often similar to normal, simply moved into the right chest. Consequently, imaging planes are similar to those used in levocardia but centered over the right chest. Dextrocardia and mesocardia are associated with heterotaxy syndrome and congenitally corrected transposition. The defects tend to be more complex and very different imaging planes are usually required to display the anatomy.

SEGMENTAL ANALYSIS

Once the general location of the heart is determined, one can proceed with the segmental analysis.^{1,3} The heart is composed of three main segments: the atria, the ventricles, and the great arteries (Fig. 105-4). These main segments are joined—like bricks with mortar—by two connecting segments: the atrioventricular canal between

FIGURE 105-4 ■ The heart is composed of three main segments (the atria, ventricles, and great arteries) joined by two connecting segments (the atrioventricular [AV] canal and conus or infundibulum). The three main segments are not directly connected to each other. If they were, the spectrum of congenital heart defects might be more limited. The atria and ventricles are joined by the AV canal, which provides the AV valves, the membranous septum, and much of the fibrous insulating material that separates atrial and ventricular muscle (except at the AV penetrating bundle). The ventricles are joined to the great arteries by the conus or infundibulum. This connecting segment, derived from the primitive outflow, undergoes initial elongation, rotation, and subsequent shortening that usually results in normally related great arteries. If abnormal, it can be associated with one of the various anomalies of ventriculoarterial alignment and connection.

the atria and ventricles, and the conus or infundibulum between the ventricles and great arteries. The three main segments, although independent and relatively autonomous, develop harmoniously the great majority of the time. The location or situs and the internal organization of the segments are strongly correlated, but each segment can vary independently of the others.

Segmental Situs

First, the situs (location) and organization of each main segment is determined.⁶ The atrial situs is either solitus or usual, inversus or the mirror image of usual, or ambiguous where the identities of the atria are unclear or ill defined. The right atrium is right-sided and the left atrium left-sided in situs solitus. In situs inversus the right atrium is left-sided and the left atrium is right-sided with opposite right-left organization (Fig. 105-5). However, the anterior-posterior and superior-inferior organization is unchanged. Consequently, the superior vena cava arises from the superior aspect of the right atrium posterior to the atrial appendage and the inferior vena cava from the inferior aspect in both cases. *Situs ambiguus* is used to describe the heterotaxy syndromes (e.g., asplenia, polysplenia syndromes), which are also called *atrial appendage isomerism syndromes*. (It should be noted that these are not identical populations or concepts.)

Criteria for identifying the right atrium (Fig. 105-6), in an approximate order of reliability, include: (1) receives the coronary sinus, (2) has pectinate muscles extending to the vestibule of the atrioventricular valve, (3) receives

FIGURE 105-5 ■ **A**, The opened right atria of two hearts, one in situs solitus (*right*) and one in situs inversus (*left*). The atria are mirror images: there is left-right inversion but no superior-inferior or anterior-posterior change. Using the fossa ovalis (FO) as a reference point, the superior vena cava (SVC) is directed superior and rightward in situs solitus but superior and leftward in situs inversus. The coronary sinus (CS) is leftward and inferior in situs solitus but rightward and inferior in situs inversus, and the tricuspid valve (TV) is to the left in situs solitus but to the right in situs inversus. In both cases the inferior vena cava (IVC) is inferior to the fossa, and the right atrial appendage (RAA) is anterior to the superior vena cava (imagine closing the atrium by folding the right atrial appendage in front of the plane of the image). **B**, The opened left atria of the same two hearts placed back-to-back but with the situs solitus heart to the left and the situs inversus heart to the right (opposite placement to panel **A**) for clarity of labeling. Note the mirror image organization of the atria. The pulmonary veins (PVs) adjacent to the atrial septum are posterior to septum primum (SP) in both cases, but rightward in situs solitus (*left*) and leftward in situs inversus (*right*). The left atrial appendage (LAA) is superior to septum primum, but it points anterior and leftward in the situs solitus heart (*left*) but anterior and rightward in the situs inversus heart (*right*). L, Left; LV, left ventricle; R, right; S, superior.

FIGURE 105-6 ■ The opened right atrium (*lower right*) and a section from a waxed, distended heart specimen (*upper left*) illustrate the characteristic right atrial features: coronary sinus (CS), pectinate muscles (PM) extending around the vestibule of the tricuspid valve (TV), inferior vena cava (IVC), septum secundum (SS) or superior limbic band on the septal surface, and large triangular appendage (RAA) with broad communication with the body of the atrium. L, Left; S, superior.

FIGURE 105-7 ■ The opened left atrium (*lower right*) and a section from a waxed, distended heart (*upper left*) illustrate the characteristic left atrial features: smooth walls with the pectinate muscles confined to the left atrial appendage (LAA), septum primum (SP) or primary atrial septum on the septal surface, and a small, finger-like appendage with a narrow junction (*arrows*) with the body of the atrium. MV, Mitral valve; R, right; S, superior.

the inferior vena cava, (4) has septum secundum on the septal surface, and (5) has a large, triangular appendage with a broad orifice communicating with the atrium. If the coronary sinus is present, it is an extremely reliable marker because it develops from the sinus horn contralateral to the one that forms part of the right atrium. Unfortunately, it is often absent (or unroofed) in heterotaxy syndromes, where most help is needed to identify the atria. The pectinate muscle morphology appears to be reliable as well but can be difficult to detect with

current imaging technology. The inferior vena cava is a useful practical marker for the right atrium but it can also drain to the coronary sinus and is often interrupted in heterotaxy syndromes.

Criteria for the left atrium (Fig. 105-7) include (1) smooth walls with pectinate muscles confined to the atrial appendage, (2) septum primum on the septal surface, and (3) small, finger-like appendage. Practically, if one can identify the right atrium, the other atrial chamber is the left atrium. If one cannot clearly identify the right atrium, the

FIGURE 105-8 ■ A series of coronal sections of a black blood magnetic resonance sequence in an infant with a heterotaxy syndrome to illustrate the variability of organ symmetry and placement often seen in these syndromes. The directional indicator at the upper left applies to all images. **A**, Symmetrical bronchi of right-sided morphology (compare with Fig. 105-1A). The upper lobe bronchi arise a short distance after the carina on both sides in contrast to the long, unbranched bronchi seen in Figure 105-1A. **B**, Dextrocardia with near absence of atrial septum. Only a small strand of the atrial septum (arrowhead) remains. **C**, The inferior vena cava (white arrow) is right-sided, whereas the superior vena cava (yellow arrow) is left-sided. The stomach (arrowhead) is left-sided. **D**, Large, symmetrical liver (arrows) spans the upper abdomen. The gall bladder (arrowhead) is left-sided. L, Left; S, superior.

situs is likely ambiguous. The superior vena cava and pulmonary veins are not reliable markers of atrial identity.

In some hearts the atrial anatomy is difficult to discern. These are generally hearts with heterotaxy syndrome (see Figs. 105-1 and 105-8). The coronary sinus is usually absent or unroofed. The inferior vena cava often changes sides in the liver and hepatic veins enter the atrial floor separately. The atrial septum is poorly represented, with only a muscular strand of tissue remaining. The atria can exhibit similar pectinate muscle morphology, but the appendages are rarely similar in size and shape. In such cases, it is best to indicate that the atrial morphology is ambiguous and to describe the anatomy in detail.

The ventricular situs or loop is either solitus or d-loop, or inversus or l-loop. Rarely (most often in double-inlet right ventricle), it is impossible to determine the ventricular loop, which is then listed as unknown (X).

The definition of the ventricular loop or situs is based on internal organization or chirality of the ventricles and not on their locations. *Left* and *right* should be considered

as the names of the ventricles rather than an indication of location. Consequently, constructions such as *morphologically left ventricle* are superfluous. The analysis of chirality is most conveniently performed on the right ventricle because the inflow and outflow are separated by an angle of nearly 90 degrees, but it can be done on either ventricle. A d-loop or solitus right ventricle is organized with the inflow from the right and the outflow to the left as viewed from the free wall; an l-loop or inverted right ventricle is organized oppositely. A simple way to understand the organization of the ventricle is to imagine which hand can be used to describe the ventricle if the thumb represents the tricuspid valve, the fingers the outflow tract, and the palm is against the septal surface (Fig. 105-9A). Only the right hand works for a solitus or d-loop right ventricle. Only a left hand works for an inverted or l-loop right ventricle.

The left ventricle is organized oppositely (see Fig. 105-9B). The left hand describes a d-loop or solitus left ventricle and the right hand an inverted or l-loop left

FIGURE 105-9 ■ **A**, The opened right ventricles of two hearts, one with solitus or d-loop ventricles (*lower right*) and one with inverted or l-loop ventricles (*left upper*). The chirality or handedness of the two right ventricles is opposite, as illustrated by the hand required to describe the ventricle. A right hand describes the d-loop ventricle on the right, with the thumb in the tricuspid valve, the fingers in the outflow and the palm against the septum. The l-loop right ventricle is organized oppositely and requires a left hand to describe it. **B**, The opened left ventricles of two hearts, one with solitus or d-loop ventricles (*lower right*) and one with inverted or l-loop ventricles (*left upper*). As for the right ventricles in the previous figure, the chirality or handedness of these left ventricles is opposite. A left hand, with the thumb in the mitral valve, the fingers in the outflow, and the palm against the septum, describes the d-loop left ventricle (*right*), whereas a right hand is needed for the l-loop left ventricle (*left*). Comparing this figure with the previous one shows that in both d-loop and l-loop ventricles, the left and right ventricles are organized oppositely: the d-loop right ventricle is right-handed while the d-loop left ventricle is left-handed; in l-loop ventricles the organization is opposite, the right ventricle is left-handed and the left ventricle is right-handed. *White arrow*, Papillary muscles on left ventricular free wall. *Ao*, Aorta; *ATL*, anterior tricuspid leaflet; *L*, left; *MV*, mitral valve; *PA*, pulmonary artery; *R*, right; *S*, superior.

ventricle. The septal wall of the left ventricle is present and identifiable even when there is only an outflow chamber or infundibulum, and no right ventricle, present on the other side. Consequently, one can use the hand rule even in cases of double-inlet left ventricle and

FIGURE 105-10 ■ Characteristic features of the right ventricle are illustrated in this opened specimen of a d-loop right ventricle: (1) trapezoidal shape bounded by the tricuspid annulus to the right, the diaphragmatic wall inferiorly, the apex and anterior wall to the left, and the pulmonary valve superiorly; (2) coarse trabeculations; (3) multiple attachments of the medial or septal tricuspid leaflet (MTL) to the septum; (4) division into an inflow or body (B) portion below the papillary muscle of the conus (PMC) and an outflow or infundibulum (Inf) above (the muscular crest marking the division between the two is composed of the septal band [SB], parietal band [PB], and moderator band [divided in this specimen]); and (5) discontinuity between the pulmonary valve (PV) and tricuspid valve because of intervening conal muscle (parietal band). *L*, Left; *S*, superior.

tricuspid atresia where there is generally only one ventricle. Conversely, in cases of double-inlet right ventricle where no left ventricle is found, it may be impossible to identify the septum.⁷ In such cases, the hand rule cannot be applied and the ventricular loop cannot be determined.

The morphologic features of the normal right ventricle include (Fig. 105-10) (1) trapezoidal shape; (2) coarse trabeculations; (3) a body or sinus portion and an outflow or infundibulum demarcated by a muscular crest composed of the parietal band, septal band, and moderator band; (4) a tricuspid valve with chordal insertions on the ventricular septum; and (5) tricuspid valve–pulmonary valve discontinuity owing to intervening infundibular muscle. The characteristic features of the left ventricle include (Fig. 105-11) (1) ellipsoidal or bullet shape; (2) fine trabeculations on the free wall and apical septum, with a smooth mid and basal septum; (3) adjacent inflow and outflow tracts; (4) two well defined papillary muscle groups originating from the free wall; (5) absence of septal insertions of the mitral valve; (6) an outflow tract between the medial leaflet of the mitral valve and the ventricular septum; and (7) fibrous continuity between the mitral and aortic valves.

The great artery position or situs is a little more complicated because there are more possibilities. First, consider situations in which the great arteries are normally related—to each other and to the ventricles. This can occur in situs solitus or the usual position of the great arteries (solitus normally related great arteries), where the aorta is posterior and rightward of the pulmonary

FIGURE 105-11 ■ Characteristic features of the left ventricle are shown in this specimen: ellipsoidal shape, smooth basal septal surface (Sp) with fine apical and free wall trabeculations, adjacent and nearly parallel inflow (dashed white arrow) and outflow (solid white arrow), two free-wall papillary muscle groups (white arrowheads) receiving chordal insertions of the mitral valve (yellow arrows), absence of septal insertions of the mitral valve, the outflow tract lying between the septum and the medial leaflet of the mitral valve (between yellow arrows), and fibrous continuity (asterisk) between the mitral and aortic (AoV) valves. R, Right; S, superior.

FIGURE 105-12 ■ The proximal aorta (Ao) and pulmonary artery (PA) from two hearts, one with solitus normally related great arteries (right) and one with inversus normally related great arteries (left). In the solitus great arteries (right), the aorta is rightward and posterior to the pulmonary artery and forms an arch (curved arrow), whereas the pulmonary artery is anterior and leftward with the bifurcation (bifurcating arrows) to the left. Conversely, in inversus normally related great arteries (left) the aorta is posterior and leftward, whereas the pulmonary artery is anterior and rightward with the bifurcation (bifurcating arrows) to the right. The pulmonary branch that passes posterior to the ascending aorta is the right pulmonary artery in situs solitus but the left pulmonary artery in situs inversus. BCA, Brachiocephalic arteries; L, left; S, superior.

artery and aligned with the left ventricle, or in situs inversus or the mirror image of usual (inversus normally related great arteries), where the aorta is posterior and leftward of the pulmonary artery and aligned with the left ventricle (Fig. 105-12). In both cases, the pulmonary

artery is aligned with the right ventricle. In situs solitus, the pulmonary artery bifurcation is to the left of the ascending aorta, whereas in situs inversus it is to the right.

Now consider situations in which the great arteries are abnormally related to each other or the ventricles. These malpositions of the great arteries are named according to the position of the aorta. If the aorta is to the right of the pulmonary artery, it is called *d-malposition* (*d* = dextro), to the left of the pulmonary artery is called *l-malposition* (*l* = levo), and directly anterior is called *a-malposition* (*a* = anterior). The term *p-malposition* has been used to describe cases in which the aorta is posterior to the pulmonary artery, mostly in rare cases of transposition of the great arteries. Malposition is a general and nonspecific term that includes all great artery arrangements, except solitus or inversus normally related great arteries.

Some hearts have only a single arterial trunk. In such cases, it makes no sense to describe its position because there is no other arterial root as a reference. An example is truncus arteriosus in which there is only the truncal root. The arterial arrangement in these hearts can be considered a form of normally related great arteries ($\{L,D,S\}$ or $\{L,L,I\}$). The same approach can be used for tetralogy of Fallot with aortopulmonary collaterals and no pulmonary trunk. The truncal root or aorta overrides the septum and is in fibrous continuity with the mitral valve (and often the tricuspid valve); this is much like the aorta in tetralogy of Fallot. Consequently, it seems reasonable to consider the arterial arrangement in these hearts a form of normally related great arteries.

There are other hearts with a single arterial trunk in which this is not the case. In rare cases of truncus arteriosus, the truncal root is completely related to the right ventricle and there is a complete subtruncal conus. Clearly, this is not a variation of normally related great arteries. Similarly, some hearts have a right ventricular aorta with subaortic conus and long-segment pulmonary atresia. This is surely not normally related great arteries, but what is it? One could assign it as transposition or double-outlet right ventricle with pulmonary atresia, but this seems arbitrary because there is no pulmonary trunk. The most accurate description is a single right ventricular arterial root—either truncus or aorta. An arterial position is not assigned because there is no other root for comparison, so that the third member of the segmental set is either left blank or assigned an X for unknown.

Practical criteria for identifying the great arteries include: (1) the aorta forms an arch and gives rise to at least some of the brachiocephalic arteries and (2) the pulmonary artery bifurcates into right and left branches (see Fig. 105-12); however, there are significant exceptions. The aortic arch can be interrupted; one or even both branch pulmonary arteries can arise from the ascending aorta; a branch pulmonary artery can be absent; the left pulmonary artery can arise distally from the right pulmonary artery in left pulmonary artery sling syndrome.

Set notation is used to summarize the situs of the three main segments (Fig. 105-13). The first element of the set is the atrial situs: *S* for solitus, *I* for inversus, or *A* for ambiguous. The second element is the ventricular situs or

FIGURE 105-13 ■ Segmental set notation used to describe the segmental situs of the main cardiac segments. The first member of the set is the atrial situs: solitus (S), inversus (I), or ambiguus (A). The second member is the ventricular loop or situs: dextro (D), levo (L), or unknown (X). Finally, the situs of the great arteries is the third member: S and I are used only for normally related great arteries; D, L, and A are used for malpositions of the great arteries, where the letter refers to the location of the aorta, right, left, or anterior, respectively. In cases with a right ventricular single arterial root, the third element of the set is either blank or an X, indicating that it is not possible to assign arterial position.

loop: *D* for solitus or d-loop, *L* for inversus or l-loop, or, rarely, *X* for unknown loop. The third element is the great artery position: *S* or *I* for solitus or inversus normally related great arteries, respectively; *D*, *L*, or *A* (some include *P*) for the various malpositions; or blank or *X* for hearts with a right ventricular single arterial root.

Segmental Alignments

Next, the alignments of the segments are defined based on what is aligned with or drains into what. Chambers are aligned if blood flows from one to the other (e.g., from right atrium to right ventricle in the normal heart). Alignment is concordant if the aligned segments are appropriate (e.g., right atrium aligned with right ventricle, or left ventricle aligned with aorta), or discordant if inappropriate (e.g., left atrium with right ventricle, or left ventricle with pulmonary artery). The concept of concordant and discordant alignment is useful when it works, but it is not universally applicable.⁸ Is the ventriculoarterial alignment in double-outlet right ventricle concordant or discordant? It is concordant for the pulmonary artery but discordant for the aorta. What about the left ventricle? What is the atrioventricular alignment in straddling atrioventricular valve?

In fact, alignment is more complicated than simply concordance or discordance, because the blood must pass through the connecting segments before reaching the distal chamber or vessel; this adds a layer of variability and complexity. There are five basic types of atrioventricular alignment, determined by the situs of the atria and ventricles and the anatomy of the atrioventricular canal (Fig. 105-14):

1. Concordant—the atria are aligned with the appropriate ventricle through separate or a common atrioventricular (AV) valve ({S,D,_} or {I,L,_})
2. Discordant—the atria are aligned with the inappropriate ventricle through separate or a common AV valve ({S,L,_} or {I,D,_})
3. Straddling AV valve (including double-outlet atrium)—one atrium is aligned with one ventricle and the other with both ventricles

4. Double-inlet ventricle—both atria are aligned with one ventricle through two AV valves or a common AV valve, and
5. AV valve atresia—only one atrium is aligned with a ventricle and the other atrium drains across the atrial septum (Note that straddling of the remaining AV valve is possible in the context of AV valve atresia.)

There are five basic types of ventriculoarterial alignment (Fig. 105-15):

1. Concordant—both great arteries are aligned with the appropriate ventricle
2. Transposition (discordant)—the great arteries are on the opposite side of the septum from normal (i.e., aorta from right ventricle or infundibulum and pulmonary artery from left ventricle)
3. Double-outlet ventricle—both great arteries arise completely or nearly completely from one ventricle
4. Straddling single arterial trunk (sometimes considered a form of normally related great arteries and, therefore, concordant)—both ventricles are aligned with (eject into) a single arterial root, and
5. Right ventricular single arterial trunk—only the right ventricle is aligned with an arterial root and the left ventricle ejects across the ventricular septal defect

Concordant ventriculoarterial alignment includes normally related great arteries (in situs solitus and inversus), anatomically corrected malposition, isolated ventricular discordance, and isolated infundibuloarterial discordance (see Fig. 105-15A). In these, the sequence of blood flow is normal—from the left ventricle to the aorta and from the right ventricle to the pulmonary artery. However, the connection of the left ventricle to the aorta is abnormal in anatomically corrected malposition (see below, Segmental Connections).⁹

Transposition indicates that the great arteries arise on the opposite side of the ventricular septum from normal—the pulmonary artery from the left ventricle and the aorta from the right ventricle or outlet chamber.^{10,11} Although there is a strong association between transposition and anterior placement of the aorta, this is not the meaning of the term. It is possible to have transposition with side-by-side vessels or even a posterior aorta.^{12,13}

Double-outlet ventricle indicates just what the name says—both great arteries arise completely or nearly completely above one or the other ventricle. Although the “50% rule” is often used to define double-outlet ventricle,¹⁴ its only attractive feature is that it simplifies cardiac bookkeeping. It has little or no clinical significance and is of no help in clinical decision making. Because it seems important for names of defects to be clinically meaningful, we do not use the 50% rule.

Single arterial trunk includes hearts with truncus arteriosus and pulmonary atresia. The aorta (or truncus) can be aligned with both ventricles (e.g., tetralogy of Fallot with pulmonary atresia or usual truncus) or only with the right ventricle (e.g., truncus with complete conus, pulmonary atresia with right ventricular aorta). Note that in aortic atresia, there is virtually always a hypoplastic ascending aorta and aortic root that sits above an atretic ventricular outflow tract and supplies the coronary
